Part of the water of the Yssel Lake is used in pushing back the saltwater wedges in the rivers and canals. This will be possible on a greater scale after the Delta Project has been completed. Here we must try to achieve our aim using the minimum quantity of fresh water. A careful study of the phenomena in the transition zone between the fresh and the salt water is therefore in progress. We are here in another borderland: that between hydrology and hydraulic research.

I have not yet spoken of ground-water hydrology. I should mention two examples of this branch of hydrology; (1) the water supply for our cities, in the sand dunes along the coast, and (2) the circulation started by the reclamation of very low areas.

In the dunes the problem was originally determining the maximum amount of water that could be taken out, without upsetting the equilibrium between the fresh water bubble (Ghyben-Henzberg lens) and the sea water underneath. When it appeared that more would be needed, the problem arose how to replenish the stored amount by water from the rivers.

A very intensive hydrologic study, including boring of hundreds of observation wells, is being made of the underground flow towards the new polders of the Zuider Zee scheme. Marginal areas would suffer, if lakes which serve as buffer-zones were not conserved along the former coast. The levels of those lakes have to be adjusted to summer and to winter conditions in order to maintain satisfactory ground-water levels in the farm lands around the Zuider Zee.

A buffer lake will also be made between the areas yet to be reclaimed and Amsterdam. If this were not done, the ground-water table under that city would possibly be lowered to a level below the tops of the wooden piles on which it has been built. Consequently those piles would rot away. There is a nursery rhyme in the Netherlands:

> Amsterdam die grote stad
> Die is gebouwd op palen
> En als die stad eens ommeviel
> Wie zou dat dan detalen?

meaning:

> Amsterdam, that city big
> Has been built on piles
> And if the city would fall down
> Who then should pay for it?

If the hydrologists should make a capital error, it is evident that the *Zuiderzeewerken* would have to pay.

Ladies and Gentlemen, I hope you are convinced why a civil engineer in the Netherlands may be involved in geophysics. From the very start we realized that we could not do anything without international cooperation. That is why we are rather active in the IUGG and why we established so many contacts with the AGU. We consider your *Transactions* as the leading publication in this field and we are happy to have so many friends among your members.

I am proud to be the second Dutchman to receive the William Bowie Medal and I thank you with all my heart for the award.

Waterloopkundig Laboratorium, Raam 61, Delft,
The Netherlands

Tests of a New Submarine Gravity Meter*

F. N. SPIESS AND G. L. BROWN

Abstract—Comparisons of the LaCoste and Romberg submarine gravity meter with the Vening Meinesz pendulum gravity apparatus have been carried out on board USS *Tilefish* and USS *Baya*. Discrepancies between measurements made simultaneously with the two instruments show a root mean-square value of about three milligals, indicating that the gravity meter is an adequate replacement for the pendulum equipment with the added advantage of improved ease of obtaining numerical results at the conclusion of each observation.

Introduction—A recent paper [*Harrison, Brown*, and *Spiess*, 1957] has described the University of California Institute of Geophysics program of gravity measurements at sea during 1954 and 1955 using the Vening Meinesz pendulum apparatus. During this time the LaCoste and Romberg Company had under development a series of modifications of their standard spring-type gravity meter in order to adapt it for use in submarines. As their program neared completion it was possible to integrate the field testing of their equipment into the Institute of Geophysics work. In particular two series of tests were made, and are reported here. The first consisted in the reoccupation of pendulum stations made along the Pacific Coast. Discrepancies were not unreasonable, particularly in view of the inclusion of errors in navigation which could contribute to lack of agreement through differences in location and in Eötvös correction. The second tests were carried out on board USS *Baya* during a cruise from Hawaii to San Diego. In this case both the LaCoste and Romberg meter and the Vening Meinesz pendulums were operated simultaneously in order that the data could be compared before making the corrections for submarine depth and speed, and with knowledge that the observations were averaged over the same geographical location.

Equipment—The only apparatus previously in regular use for the measurement of gravity over the deep sea is the pendulum equipment of Vening Meinesz, operated in a submerged submarine. This equipment, then, can provide a check on the accuracy of other methods and also will set the standard of accuracy and ease of operation against which other methods must be judged. This equipment has been described by *Vening Meinesz* [1929, 1941] in two publications, and has remained unaltered since about 1938 by all users except for improvements in timing methods and in the auxiliary equipment [*Worzel* and *Ewing*, 1950, 1952; *Browne* and *Cooper*, 1950; *Cooper*, 1949]. The particular variants used in the work described here are discussed in detail by *Harrison, Brown*, and *Spiess* [1957].

The LaCoste and Romberg submarine gravity meter is shown in Figure 1. The basic sensing element is of the type of the LaCoste long-period seismograph [*LaCoste*, 1934, 1935], employing a carefully designed and constructed spring which has very close to linear response over a range of deflections corresponding to several thousand milligals change in acceleration. The sensing element is a null reading device; the point of attachment of the spring to the frame is altered by motion of a calibrated screw in order to return the meter beam to its zero position. A light transmission and photocell arrangement very similar to that used in the LaCoste and Romberg earth-tide gravity meters determines the direction and amount of deflection of the beam from its zero position, thus providing the signal for remote indication [*Clarkson* and *LaCoste*, 1957]. The beam position is indicated directly on a beam position microammeter and in an integrated form on a timing indicator microammeter.

The sensing element is mounted in a gimbal system which holds the element's orientation along the instantaneous apparent vertical. In order to provide a high degree of damping without increasing the static friction in the gimbals (as would occur if mechanical frictional damping were employed) an electrical servo system with the desired transient response is used. The result is that the instrument follows the apparent vertical closely, and the output of the sensing element is thus a measure of the magnitude of the vector sum of the force of gravity and the apparent force caused by the acceleration of the platform. The result of averaging such a reading, as was first pointed out by *Browne* [1937], is that a first-order

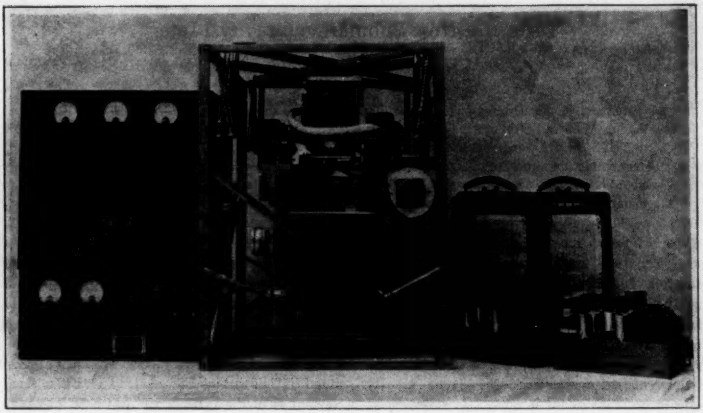

FIG. 1 - Submarine gravity meter

correction must be made for the net vertical acceleration (difference in vertical velocity) over the entire observation, and a second-order correction for the mean-square value of the horizontal acceleration over the averaging period. Long-period pendulums were devised by *Vening Meinesz* [1941] for use with the original pendulum equipment to provide information for computation of the second-order correction. A similar pair of long period pendulums is used in connection with the LaCoste and Romberg instrument for this purpose.

In contrast with the operation of the Vening Meinesz equipment, the apparent deflections of the two long-period pendulums in the LaCoste meter are measured electrically and fed continuously into a circuit which computes the second-order horizontal acceleration correction automatically. This computed correction is subtracted from the measuring screw reading by means of a differential gearbox to give a corrected gravity reading. The gravity reading can be changed by the operator, using a remote electrical control, and is continuously recorded in digital form by an Esterline Angus operational recorder using 16 binary digits. The gravity reading remains constant between alterations, but the measuring screw reading varies continuously during an observation at sea as the second-order correction changes. The effectiveness of this approach has been verified by laboratory tests in which the instrument was operated on a movable platform subject to horizontal accelerations having periodicity ranging from 7 to 15 sec and root mean-square (rms) amplitude ranging from 4000 mgal at short periods to 1200 mgal at the long periods (second order corrections of 8 mgal to 0.7 mgal). The resulting readings, including the second-order correction, were all within 0.5 mgal of the value obtained when the instrument was operated with no motion. The first-order correction was determined independently of both the pendulum and meter equipments using the depth recorder described by *Harrison*, *Brown*, and *Spiess* [1957].

Actual gravity measurements are made in a submerged submarine operating under reasonably stable conditions. Once the submarine is at the chosen depth the gimbals are freed and the gravity meter beam unclamped. The operator adjusts the gravity reading until the beam is very nearly in equilibrium, but so that its average position as shown on the timing indicator is moving slowly towards the null point. The Esterline Angus recorder is marked as the timing indicator passes through zero and, after several minutes, the gravity reading is again adjusted to make the timing indicator move towards zero. This procedure is repeated for about 30 min. The observed value of g is obtained by averaging the gravity reading shown on the Esterline Angus record, between the first and last times that the timing indicator crossed its zero position. This averaging only takes a few minutes so that g is obtained very shortly after the observation is completed. In the tests which are reported here the same averaging time (about 30 min) as that used with the pendulum equipment was employed; however, computations were made for smaller intervals within this period and these seemed to indicate that very often a satisfactory value could be obtained in as little as 15 min.

On the cruise on which they were operated simultaneously the meter and the pendulums were both located in the forward torpedo room, within 15 ft of one another. The pendulums were mounted about amidships with the plane of swing athwartships. The meter was slightly aft on the starboard side.

Sea tests—The first of the two test series reported here was conducted on board USS *Tilefish* in March 1955. Since these tests were the first at sea following extensive alterations and improvements on an earlier model, it was felt that the additional effort needed to install and operate both the LaCoste and Romberg and the pendulum equipments simultaneously would not be justified. Instead, several previously occupied gravity stations off the west coast of the United States were reoccupied (as closely as navigational accuracy would allow) for comparison purposes. The gravity meter counter readings were converted to milligals, corrected for instrument drift, submarine depth, and Eötvös effect, and compared with the international gravity formula values for the actual latitude of observation to give free-air anomalies. The calibration factor used was four parts in 1000 less than that determined by the manufacturer. This calibration is based on independent observations made by A. A. Day and J. C. Harrison with two later models of the LaCoste and Romberg submarine gravity meter. The measured differences of gravity between UCLA and the University of Washington at Seattle were compared with the differences established with Worden gravity meters.

The factors indicated for both meters were four parts in 1000 less than those supplied by the manufacturer. Base points for determining the actual values of *g* and the drift were 979,549.6 mgal at the Marine Physical Laboratory in San Diego and 980,738.9 mgal at the University of Washington in Seattle, the former determined by J. C. Harrison (private communication) and the latter by A. A. Day (private communication). The total drift for the cruise was +2.0 mgal. In Table 1 the free-air anomalies determined in this fashion are compared with the free-air anomalies at the corresponding nearby pendulum stations [*Harrison*, *Brown*, and *Spiess*, 1957]. No attempt was made to calculate the differences in topographic corrections which might arise from the slightly different locations of the meter and pendulum stations, thus these, as well as any navigational uncertainties, are included in the discrepancies listed. The resulting mean difference of 1.1 mgal and rms difference of 4.3 mgal are strongly controlled by a single station, no. 49, at which the difference is 11.4 mgals.

Results of the *Tilefish* tests were sufficiently good to encourage the execution of further, more elaborate tests. These became possible when Commander Submarines, Pacific Fleet, made USS *Baya* available for gravity work on a transit from Hawaii to San Diego in October of 1955. In addition to check observations at the Bishop Museum in Honolulu and at the Institute of Geophysics two groups of stations were made, each along a north-south line across the Murray Fracture zone, one at longitude 152°30′W and the other at 133°30′W.

TABLE 1 – *Comparisons of LaCoste and Romberg gravity meter values with previously occupied Vening Meinesz pendulum stations USS Tilefish, April 1955*

Number of nearby pendulum stations[a]	Free-air anomaly by pendulums	Free-air anomaly by gravity meter	Difference, pendulum − gravity meter value

124	980,520.0	980,518.2	+1.8

Mean difference = 1.9 mgal (exclusive of Station 110A); rms difference = 3.3 mgal.

Base for pendulum values: UCLA, Geology-Chemistry Building, Room 1275, 979,597.6 mgal.

Bases for gravity meter values: UCLA, Geology-Chemistry Building, Room 1275, 979,597.6 mgal, and Bishop Museum, Honolulu, 978,952.6 mgal.

Calibration factor 0.9960 × manufacturer's.

Gravity meter drift −1.8 mgal.

[a] For position of stations, see *Harrison*, *Brown*, *Spiess* [1957].

In this case again the calibration factor used was four parts in 1000 smaller than that of the manufacturer and the values 978,952.6 for Bishop Museum [*Bonini* and *Woollard*, 1957] and 979,597.6 for UCLA (J. C. Rose, private communication) were used as the gravity meter base stations, with a resulting −1.8 mgal drift being indicated. The observed gravity values, corrected neither to sea level nor for Eötvös effect, are listed for both the meter and the pendulums in Table 2. The rms value of the differences (excluding station 110A which will be discussed below) is 3.3 mgal.

During this trip, however, two sorts of difficulties were experienced and each of these will be discussed below.

The first difficulty was manifested only at stations 101 and 110A. At station 101 the gravity meter was in operation for about 25 minutes prior to the start of the pendulum observation. During the first 20 minutes of that time a consistent reading was obtained. Shortly after that a sudden drif of 17.4 mgal was observed. The gravity mete reading thereafter was steady and, during th pendulum observation, was as listed in Table where an error of −4 mgal is shown. At statio 110A a 17 mgal discrepancy between the two instruments is shown. In this case the major portio of the error must be ascribed to the gravity mete since stations 110A and 110B were run on heading east and west respectively in order to calibrat ship's speed through the water from the differenc in Eötvös effect. A similar reversed pair of station was made at 123A and 123B. The ship's spee calculated from the pendulums was realistic i both cases while that from the gravity meter wa in agreement at 123A-B but was out by a factor o 3 at 110A-B. When the gravity meter was returne to the factory, a corroded resistor was found nea an opening in the case, and shorting out thi resistor produced an 18-mgal change in reading. I thus seems reasonable to conclude that moistur on this resistor produced an intermittently erroneous reading, and a minor alteration in circuit layou has subsequently been made to eliminate possibl recurrence of this trouble.

The second difficulty was of a fundamentally different type, and was made apparent chiefly because a casualty in the air conditioning circulating water piping on the *Baya* forced her Commanding Officer to restrict operations to 200 ft submergence depth or less. At stations 111 through 122 a swell of 17- to 18-second period existed with acceleration amplitudes of 5000 to 9000 mgal as computed from long-period pendulum records. This particular gravity meter will not operate properly when subjected to vertical accelerations with amplitude greater than about 6000 mgal at a period of 10 sec, 4000 at 15 sec, or 3300 at 18 sec. As a result no readings were obtained at these 12 stations. If the full normal operating depth of the *Baya* could have been used, only one or two stations would have been lost. An examination of the pendulum records from the cruises reported by *Harrison*, *Brown*, and *Spiess* [1957] indicates that no more than five stations in 125 would have been lost if operating depths down to those normally available in submarines at present in operation by the U. S. Navy had been used. While these acceleration limits exist for the meter tested they have been greatly extended in later models.

Stations 98 and 100 are not listed because excessive vibration of the submarine led to very large middle pendulum amplitudes and the pendulum observations could not be reduced for these two stations. Gravity meter readings were obtained at these locations.

Conclusions—It is difficult to assess the meaning of the results of these two sets of observations unless some standard is available against which they can be judged. As far as the authors are aware, two sets of Vening Meinesz pendulums have never been operated simultaneously at sea, but data are available for successive observations made with a single equipment at one particular location. *Browne* and *Cooper* [1950] list ten stations at which double observations were made, although one observation of the pair was always taken at a shallow depth and was thus somewhat more disturbed than would normally be expected. In these cases the rms difference is 5.8 mgal if one difference of 25 mgal is rejected. A series of station reoccupations were made by *Browne* and *Cooper* [1952] using very careful navigating techniques for determining both position and Eötvös corrections. The result was an rms scatter from the mean of 1.4 mgal which should imply an rms difference between observation pairs of 2.0 mgal. A further idea of what can be expected may be drawn from the rms scatter of base swings made on surfaced submarines alongside various moorings. UCLA Institute of Geophysics stations alongside the U. S. Navy Electronics Laboratory pier at San Diego show an rms difference from the mean of 2.8 mgal for five observations. Nine base swings at Portland, England, give a 2.7 mgal difference from the mean [*Browne* and *Cooper*, 1952] while a scatter of swings at Gosport, Simonstown, and Trincomalee has an rms value of 2.2 mgal [*Girdler* and *Harrison*, 1957]. These would lead one to expect an rms deviation from the mean of 2.5 or 2.6 mgal and a consequent difference between pairs of observations having an rms value of 3.5 mgal, somewhat larger than the 3.3 mgal for the *Baya* operation.

On the basis of this comparison, then, the scatter between gravity meter and pendulum observations is of magnitude comparable with what one might expect between two sets of pendulum equipments. In the future, however, all possible opportunities should be utilized to install and operate pairs of gravity-determining devices simultaneously on the same submarine. Data from pairs of pendulum equipments as well as pairs of gravity meters and mixed pairs will be needed if a clear measure of consistency and agreement of these two types of apparatus is to be achieved.

Although these tests show no clear cut advantage in terms of equipment accuracy, and while the gravity meter replaces the mechanical and optical complexity of the multi-pendulum equipment with increased electrical complexity and there is no advantage for either in terms of space or weight, nevertheless the ease in operating and obtaining gravity values from the meter makes it an appealing competitor.

Acknowledgments—We are indebted to F. A. Vening Meinesz for making his pendulum equipment available to us for these tests, and to L. J. B. LaCoste for the use of the gravity meter and for lending a technician to assist in its operation at sea. J. C. Harrison provided much appreciated assistance and advice on the preparation of this paper.

Acknowledgment is also due to Commander Submarines, Pacific Fleet, and his staff and in particular to the officers and men of the USS *Tilefish* and USS *Baya* for their assistance in carrying out this operation. This work was supported by the U. S. Navy through Office of Naval Research Contract Nonr 233(19) and Bureau of Ships Contract NObsr 72512, NE 120221-4-5-6.

The Use of Evenly Spaced Hemispheres to Evaluate Aerodynamic Forces on a Soil Surface

W. S. CHEPIL

Abstract—Direct and indirect measurements showed a substantial lift force on the surface roughness elements (such as soil grains resting on the surface) in a windstream. Lift was approximately four-fifths of drag on hemispherical roughness elements ranging from 0.16 to 5.08 cm in height. The ratio of lift to drag on the roughness elements of the surface remained essentially constant for any drag velocity of the fluid and any depth of the fluid boundary layer beyond a relatively shallow depth. The depth of the fluid boundary layer, on the other hand, had a profound influence on the magnitude of both lift and drag. This study throws new light on equilibrium conditions existing between soil grains and moving fluid at the threshold of movement of the grains.

A thorough understanding of the forces exerted on soil surfaces by wind is basic to the design of measures for coping with the wind erosion problem. It was desirable therefore to obtain some experimental data on the aerodynamic forces of drag and possible lift on roughness elements such as soil grains resting on the surface of the ground. This study was designed to give some information on the equilibrium conditions between the soil grains and the moving fluid at the threshold of movement of the grains. The study does not apply to forces operating on the grains during entrainment or motion.

Jeffreys [1929] suggested that fixed particles in a stream of water or air are subjected to lifting forces caused by specific pressure distributions on their surfaces. *Einstein* and *El-Samni* [1949, 1950] measured a significant lift force in a stream of water which tends to pull the natural sediment away from the surface. On the other hand, *White* [1940] concluded from an experiment with a wax grain tied to a cotton thread that the lift component of wind on a loosely packed bed of sand grains is negligibly small. The grain was prevented from moving downstream by the tension on the cotton which carried the horizontal force on the grain. The author of this paper believes that the grain could not rise perceptibly above the level of the surface even if lift was substantial, for if the grain were to rise somewhat, the force of wind higher up being many times stronger than either the forces of drag or lift at the surface would push the string with the attached grain down to an essentially horizontal position. An unattached grain or a grain attached to the loose end of the string facing upstream instead of downstream might have been lifted up as well as pushed forward.

Principles that govern lift and drag on a rough surface—According to the theory of Prandtl [*Brunt*, 1934] and *von Karman* [1934] for turbulent flow, the fluid velocity v at any height z above a rough surface over which no movement of surface material takes place can be expressed by

$$v_z = 5.75\ V_*\ \log_{10}\frac{z}{k} \tag{1}$$

where V_* is the so-called 'drag velocity' and k is the height at which the fluid velocity is zero (Fig. 1). The height k defines a theoretical surface and is constant for a given surface at all fluid velocities but varies with the height, shape, and arrangement of the roughness elements of the surface. V_* is equal to velocity at $30k/8.5$ and determines the slope of the velocity distribution curve when the velocity is plotted against the logarithm of height. The average drag τ_0 per unit of horizontal area of the entire surface may be computed from V_*, since $\tau_0 = qV_*^2$ where ρ is the density of the air, that is, the weight per unit volume of air divided by the acceleration due to gravity. The force τ_0 is dynamic acting in the direction of flow and composed of form drag and skin-fraction drag. No separation of the two forces is made in this study.

Since in turbulent flow pressure and drag vary as the square of velocity within the range of Reynolds number to which this study applies, it follows that pressure can be described with k as a linear scale for the size of the roughness elements. From this it was further concluded by *Einstein* and *El-Samni* [1949] that any convenient size of surface roughness element could be used to find the pressure distribution on its surface as long as it was sufficiently large to make the surface aerodynamically rough. It has been found by *Goldstein*

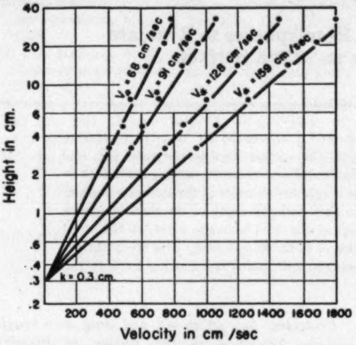

FIG. 1 – Wind velocity distributions above a fine gravel surface composed of hemispherical mounds 2.54 cm high and spaced in a hexagonal pattern three diameters (6 heights) apart.

[1938] that the critical Reynolds number $V_*r/\nu = 3.5$ distinguishes the condition under which the surface may be aerodynamically rough or smooth. In the above equation, r is the roughness (height of the particles on the surface) and ν is the kinematic viscosity of the fluid. In this investigation r is the radius of hemispherical roughness elements (Fig. 2) and ν is equal to 0.15 cm²/sec. The Reynolds number is dimensionless. If the value of the Reynolds number is smaller than 3.5, the topmost particles are submerged in a laminar sublayer to which the forces of turbulent flow do not apply. If, on the other hand, the Reynolds number is considerably greater than 3.5, the particles throw off eddies to their lee sides and disrupt the laminar layer. Of course, there is a transition state between the two flow conditions near the Reynolds number of 3.5.

Under a wind velocity equal to or greater than that required barely to move the soil particles, the particles disrupt the laminar layer if they are equal to or greater than 0.05 mm in diameter [*Chepil*, 1945]. It is significant to note that erodible soils always have a substantial proportion of particles greater than 0.05 mm. Therefore, soil movement is associated predominantly with turbulent flow of air against the particles. No upper limit can be given for the size of particles to which the forces of turbulent flow apply, but to make sure that the same effects of turbulent fluid flow apply to any size of particle greater than 0.05 mm, various sizes of surface roughness elements were used.

Procedure—A previously described wind tunnel [*Zingg* and *Chepil*, 1950] was used for measuring air velocity and the force of drag and lift on the roughness elements of the surface. An arrangement in which the air was forced through the upper-story room and recirculated to the fan was used. Pressure on the surface elements and velocity up to one foot above the average surface were measured under conditions of an expanding boundary layer at various distances downstream in the tunnel duct that was 56 ft long, 3 ft wide, and 3 ft high. At 50 ft downstream and halfway between the walls where most measurements were made, the fluid boundary layer was from 10 to 16 inches deep, depending on the height of the roughness elements of the surface. The depth of the fluid boundary layer is defined as the maximum height z to which (1) applies.

Velocity was recorded for different heights measured from the base of the roughness elements of the surface and plotted as shown in Figure 1. The theoretical surface k to which the straight-line velocity distribution curves projected ranged from $0.11r$ to $0.21r$ above the base of the roughness elements of height r, depending on the individual measurements.

The average drag τ_0 per unit of horizontal area of the entire surface was computed from V_* as already indicated. In addition, forces of average drag and lift on the roughness elements of the surface were determined directly from pressure distribution on the elements. In the initial measurements hemispheres 1.27, 2.54, and 5.08 cm high placed flat side down on the wind-tunnel floor were used as roughness elements. The pressure distribution was measured by means of a straight-tube alcohol manometer having an adjustable slope of zero to three degrees and reading to 0.0004-inch of water (Fig. 2). The positive-pressure end of the manometer was connected by rubber tubing leading through the tunnel floor and inside the hollow hemisphere to any of the nine taps (small holes) placed at various positions normal to the hemispherical surface. Starting at the base of the hemisphere, the taps were placed 30° apart along one line running parallel with and another running normal to the direction of the wind. The negative-pressure end of the manometer tube was connected similarly to a tap on top of the hemisphere. Thus, it was possible to detect and measure approximately the average lift and drag as resultant pressure

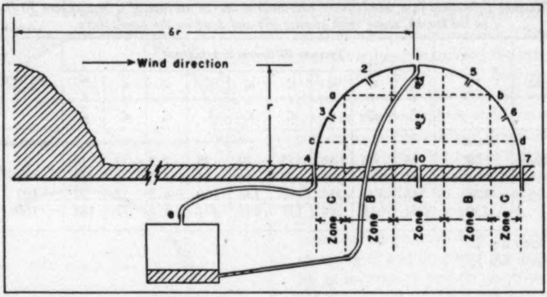

FIG. 2 – Diagrammatic representation of the method of determining pressure distribution on the hemispherica surface; for simplicity, pieces of rubber tubing connected to taps 2, 3, 5, 6, 7, 8, 9, and 10 running through the tunnel floor to be connected one at a time to the pressure end of the manometer at e, are not shown.

differences between the top and the bottom and the windward and the leeward parts of the hemisphere, respectively. Only one metal hemisphere was used to measure lift and drag while the remainder of the floor was covered with mounds of the same height and width as the hemisphere but composed of gravel 2 to 6.4 mm in diameter. It was impossible to make the mounds exactly hemispherical. These surface roughness elements were placed in a hexagonal pattern three diameters (six heights) apart. Thus, they occupied 0.11 of the total floor area. The remainder of the floor, including that around the metal hemisphere, was composed of the same gravel as that of the mounds.

The average drag per unit of horizontal area occupied by the hemisphere was taken directly as a pressure difference on the surfaces facing against and away from the wind. Let the cross-sectional areas normal to wind direction through the center of the spherical segments *ab*, *cd*, and 47 (Fig. 2) be equal to x, y, and z, respectively. The areas x, y, and z are equal to $\pi r^2\theta/360 - r^2 \sin \theta/2$ where the values of θ are the angles subtended by chords *ab*, *cd*, and 47, and r is the radius of the hemisphere. For any hemisphere, areas x, $y - x$, and $z - y$ occupy 0.183, 0.509, and 0.308, respectively, of the total cross-sectional area z. The average drag per unit of horizontal area occupied by the hemisphere therefore can be expressed approximately by

$$\tau = \frac{0.183(P_2 - P_5) + 0.509(P_3 - P_6) + 0.308(P_4 - P_7)}{2} \qquad (2)$$

where P_1, P_2, etc. are pressures at positions 1, 2, etc. as indicated in Figure 2.

The average lift per unit of horizontal area occupied by the hemisphere was determined from the average-pressure differences between the base of the hemisphere and zones A, B, and C (Fig. 2). The horizontal areas of zones A, B, and C were determined graphically to be equal to 0.062, 0.394, and 0.544 of the basal area of the hemisphere. If the average-pressure differences

$$P - P_A = \frac{(P_4 - P_1) + (P_{10} - P_1) + (P_{10} - P_1) + (P_7 - P_1)}{4}$$

$$P - P_B = \frac{(P_4 - P_2) + (P_{10} - P_8) + (P_{10} - P_8) + (P_7 - P_5)}{4}$$

and

$$P - P_C = \frac{(P_4 - P_3) + (P_{10} - P_9) + (P_{10} - P_9) + (P_7 - P_6)}{4}$$

where P is the average pressure at the base of the hemisphere and P_A, P_B, and P_C are average pressures at zones A, B, and C, respectively, then the average lift L per unit of horizontal area occupied by the hemisphere may be expressed approximately by

$$L = 0.062(P - P_A) + 0.394(P - P_B) + 0.544(P - P_C) \qquad (3)$$

Measurements were also made on gravel and wet sand mounds of the same shape and spacing

as the gravel mounds of the initial part of this study. The smallest wet sand mounds had a size equal to the largest soil particles commonly eroded by natural winds. Because the mounds were small, it was impossible to use the same method of determining lift and drag as on the hemispheres. Small hypodermic needles calibrated against a standard Pitot tube were used to measure pressure differences only between the top of the mounds (position 1, Fig. 2) and the base immediately to windward and leeward of the mounds (positions 4 and 7, respectively). The needles passing through the floor of the tunnel were imbedded in the sand or gravel in such a way that their openings were normal to and flush with the average surface. The pressure differences between positions 1, 4, and 7 were determined as in the initial study. The results with the hemispheres indicated that the pressure difference $P_4 - P_7$ represents twice the average drag per unit area on the hemisphere and the average of the pressure differences $(P_4 - P_1)$ and $(P_7 - P_1)$ is about 2.85 times the average lift per unit area on the hemisphere (Table 1). The forces of lift and drag on the mounds were taken therefore as pressure differences between the top and the bottom and the windward and the leeward positions, respectively, divided by these respective factors.

Two torsion balances accurate to five milligrams were used to measure directly the forces of lift and drag on a hemisphere suspended close to a horizontal surface in a windstream. As shown dia-

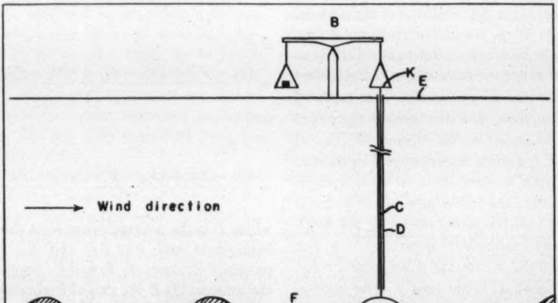

FIG. 3 – Diagrammatic sketch of apparatus for measuring drag and lift on a hemisphere.

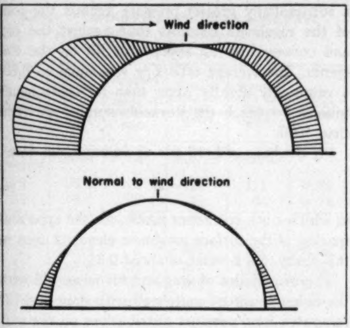

FIG. 4 – Pattern of pressure differences between position 1 on top of the hemisphere and any other position along the vertical axes parallel and normal to wind direction. Shaded areas above the circular line denote positive, and below the line negative pressure with respect to position 1; the length of lines in the shaded area denote the relative magnitudes of positive or negative pressure.

grammatically in Figure 3, hemisphere *A* was suspended from the end of the beam of balance *B* by string *C* leading through a vertical tube *D* through the tunnel ceiling *E*. One end of string *F* was connected to hemisphere *A* and led horizontally over pulley *G* and downward through the tunnel floor *H* through tube *I* to the end of the beam of balance *J*. The whole apparatus was placed approximately 54 ft downstream in the tunnel duct where, when the wind was turned on, the pressure inside the tunnel was approximately equal to the pressure outside. Consequently little or no air entered or escaped through tubes *D* and *I*. The surface on the tunnel floor was composed of gravel mounds of the same size and approximate shape as the hemisphere and arranged in the same pattern as in the initially described surfaces. The balances were leveled before the wind was turned on. After the wind was turned on, the balances again were leveled by placing appropriate weights on pans *K* and *L*. Lift on the hemisphere was registered on balance *B* by the decrease of tension on string *C* and drag was registered on balance *J* by an increase of tension on string *F*.

Lift and drag on hemispheres 3.18 cm high were determined at 3, 25, and 50 ft downwind in the tunnel duct. Measurements on all other roughness elements were made at 50 ft downwind.

Results—The pressure on the lower parts of the hemispheres was always found substantially higher than on a considerable area at and around the top. The pressure distribution (Fig. 4) was almost identical for nearly all sizes of hemispheres and wind velocities used. The actual magnitude of the pressure difference between different points on the hemisphere depended only upon the drag velocity of the fluid.

The ratio of lift to drag, L/τ was essentially constant for all sizes of hemispheres and drag velocities used except for two highest velocities on the largest hemisphere (Table 2). These latter cases had Reynolds numbers of the form $V_* r/\nu$

equal to 5298 and 6840. The average ratio of lift to drag for all other cases was 0.81. Repetition of the whole set of measurements of Table 2 produced essentially the same results as the first run of measurements.

The average drag on the hemispheres was from 4 to 6 times greater than the average drag computed from V_* for the whole surface. The ratio of drag on the hemispheres to drag on the whole surface increased slightly with the size of the hemispheres (Table 2).

The results with sand and gravel mounds, as shown in Table 3, again indicated that there was a substantially greater pressure against the foot of the roughness elements than against the top and consequently an appreciable lift on the elements. The average ratio L/τ was equal to 0.88, a value only slightly larger than for those hemispheres for which the Reynolds number was less than 5000.

Table 4 – *Concordance between average lift and drag measured with balances and computed from pressure distribution on the surface of a hemisphere 2.5 inches in diameter*

133	113	129	92	85
166	197	210	163	199

On the basis of both sets of experimental data

$$L = c\tau \tag{4}$$

in which c is a coefficient which, for the type and spacing of the surface roughness elements used in this study, has a value of about 0.85.

The magnitudes of drag and lift measured with the balances agreed quite well with drag and lift computed from pressure distributions on the surface of the hemispheres (Table 4). Since the computed values of drag are based on pressure results which measure form drag only, agreement tends to indicate that skin fraction drag is negligible in these cases.

The ratio of lift to drag was about the same at 25 and 50 ft downstream in the tunnel where the expanding fluid boundary layer was approximately 27 and 40 cm deep for hemispherical roughness elements 3.18 cm high (Table 5). The ratio of lift to drag appeared to be somewhat higher at three feet downstream in the tunnel duct than at 25 and 50 ft. The depth of the fluid boundary layer at three ft was only about 5 cm. It is evident from these results that increasing the depth of the fluid boundary layer, after a certain limit of depth has been reached, has little influence on the ratio of lift to drag. However, the depth of the fluid boundary layer had a profound influence on the magnitude of both lift and drag.

Discussion—Einstein and *El-Samni* [1949] used an equation of the form

$$\Delta p = C_L\,(\rho/2)\,u^2 \tag{5}$$

in which Δp is the pressure difference between the top and the bottom of the hemisphere and which was assumed to be the lift force on the hemisphere, and u is the fluid velocity at 0.35 hemisphere diameters away from the theoretical wall represented by height k in these experiments. Eq. (5) is applicable to a surface composed of closely packed hemispheres. Since from the experiments reported in this paper it was found that the ratio L/τ on the roughness elements of the surface remains virtually constant for any size of roughness element and drag velocity within the des-

Average	...	...	...	...	0.068

ignated range of the Reynolds number, it may be expected that the ratio of lift L_A to drag τ_0 per unit area of surface composed of closely packed hemispheres would remain constant too. If this assumption is true, lift on the closely packed hemispheres would be approximately equal to $0.85\tau_0$. On the basis of this assumption, values of L_A based on this study were substituted for those of Δp of (5) which gave an average value of C_L equal to 0.068 (Table 6) as compared with 0.178 found by *Einstein* and *El-Samni* for water. However, this discrepancy is due principally to the method of determining lift on the hemisphere. In experiments by Einstein and El-Samni, lift on the hemisphere was taken as a pressure difference between the top and bottom of the hemisphere. In these experiments, lift was computed from the pressure distribution on the hemisphere. Furthermore, from these experiments it was found that the pressure difference between the top and the bottom of the hemisphere is about 2.85 times the lift on the hemisphere. If this factor is correct, the value of C_L based on determinations by *Einstein* and *El-Samni* [1949] should be $0.178/2.85 = 0.0624$, a value only slightly smaller than the value of C_L based on these experiments. The slight discrepancy easily may be due to the differences that existed between the two studies with respect to the relative distance between the hemispheres. In the study by Einstein and El-Samni the hemispheres were closely packed; in this study they were three diameters apart. This distance was chosen to imitate the average distance that was found between sand grains removable from surfaces of loose sand beds [*Zingg*, 1952].

Conclusion—This study shows that lift on hemispherical surface projections, similar to soil grains resting on a surface in a windstream, is substantial. Therefore, lift must be recognized together with drag in determining an equilibrium or critical condition between the soil grains and the moving fluid at the threshold of movement of the grains. The ratio of lift to drag on the roughness elements of the surface remains essentially constant for any drag velocity of the fluid and any depth of the fluid boundary layer beyond a relatively shallow depth.

Acknowledgments—Grateful acknowledgment is due Robert D. Lynch for assistance during the course of this study and to C. E. Pearce for valuable suggestions on measurement of fluid pressure. Probability Distributions of Water-Wave Slopes under Conditions of Short Fetch

ALLEN H. SCHOOLEY

Abstract—Slope probability distributions were measured for a fetch of about 15 inches, using a small wind tunnel containing a water boundary. For this very short fetch, the mean-square slope was found to be higher than previous longer-fetch data for wind velocities greater than about 10 kn. At 18 kn the short-fetch mean-square slope was 70 pct higher.

Evidence of peakedness of the slope distributions was found in the short-fetch data. The mean value of the distributions was measured to reach a maximum in the downwind direction and was about 1.5° in the region of 18 kn.

Introduction—Probability distributions of slopes of wind-disturbed water surfaces for various wind velocities have been reported by *Cox* and *Munk* [1954] and by *Schooley* [1954]. The results are in reasonable agreement in the direction of the wind for wind speeds between 5 and 25 kn, even though different methods of measurement were used and the locale of the measurements was the Pacific Ocean in the first case and the Anacostia River (a tidal estuary in the District of Columbia) in the other. The fetch in the Anacostia River was about 1000 ft, which is probably several orders of magnitude less than the fetch in the Pacific. Since the fetches in the two cases were widely different, the agreement in slope distributions implies that the fetch is of secondary importance, at least for fetches greater than 1000 ft. It is the purpose of this paper to compare the measurements of slope probability distributions for an average fetch of about 15 inches with the previous longer-fetch data.

Experimental equipment—The small wind tunnel, the lower portion of which is occupied by water, previously described by *Schooley* [1955] and shown in Figure 1, was used to gather the experimental data. The total fetch, determined by the length of the lucite wind channel, was 26 inches. Wave profiles for the various wind velocities were recorded by taking 0.001-sec flash pictures focused on the front lucite-water-air intersection. Full scale enlargements were made, and the slope of the water surface was determined graphically at 0.5-cm intervals near the central portion of the pictures for a total distance of about 25 cm. At the higher wind velocities the limits of measurements were made to correspond to approximately an integral number of the longest wave length present. The average fetch in the region of measurement was about 15 inches. Figure 2 shows one of the wave-profile pictures, retouched to make the lucite-water-air boundary visible in the small illustration.

Analysis of data—The slope measurements for each wind velocity were grouped into five-degree interval histograms, and from these data cumulative frequency of occurrence points were calculated and smoothed ogive curves drawn [*Kenney*, 1947]. Points taken from the ogive curves were then replotted on linear probability paper for the various wind velocities considered. The plot for 20 kn is shown in Figure 3. Deviation of the linear probability paper plot from a straight line shows that the actual distribution is peaked because the curve has a detectable amount of sigmoid curvature. The flaring out of the actual distribution curve from a straight line in the upwind direction indicates that the distribution is skewed in the downwind direction, confirming the findings of *Cox* and *Munk* [1954]. (In this paper the slopes looking upwind are negative and those downwind are positive, which is reversed from the convention used by Cox and Munk.)

In Figure 3 the straight line representing the gaussian approximation of the actual distribution is drawn through the 16 pct and 84 pct points, which define the plus and minus standard deviation (σ) points of the gaussian approximation. The standard deviation of the gaussian approximation is considered to be one half the difference between the 16 pct and 84 pct points, and the mean-square slope is the square of the tangent of the standard deviation angle.

The mean-square slopes for the various wind velocities studied are shown in graphical form by the upper curve in Figure 4, where the mean-square slope is the ordinate and the wind velocity is the abscissa. Also shown are points taken from the relatively long-fetch results referred to previously. It is evident that for wind velocities above about 10 kn, the mean-square slope for the short-fetch waves was measured to be considerably greater than for the waves formed by longer fetches. At 18 kn it is about 70 pct higher. This interesting

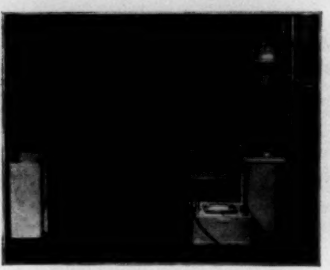

FIG. 1 – Wind tunnel with a water boundary

result may be due to the sheltering of part of the surface from the wind by the higher, longer-fetch waves, thus decreasing the amount of short-fetch waves which are the principal contributors to the magnitude of the mean-square slope.

The curved line in Figure 3 shows the smoothed cumulative frequency of occurrence for the actual distribution, which in this case is both skewed and peaked compared to a gaussian distribution. Thus it is desirable to determine the median, mean, and mode values for the actual distribution. The median slope can be determined directly from the point where the actual distribution curve crosses the 50 pct ordinate. The mean-slope value represents the distance between the zero-slope line and the center of gravity of the original histogram (not shown). Using the mean and median values, the mode may be calculated by the approximate method given by Kenney. Table 1 shows the mean, median, and mode values for the various wind velocities studied. The last column of Table 1 was based on the appearance of the actual distribution curves of the cumulative frequency of occurrence plots for the various wind velocities. A pronounced sigmoid shape was accepted as evidence that the actual distribution was peaked compared to a gaussian distribution. All the actual distributions showed evidence of peakedness except for 16 and 22 kn. Thus there is an inconclusive hint that perhaps the peakedness may become less with increased wind velocity under the conditions that the data were taken.

The functions of Table 1 are all positive, except the means at the two lowest wind velocities. This result indicates that the distributions are mostly skewed in the downwind direction. It is also evident that all three functions reach a maximum in the region between 16 and 20 kn. This would indicate that the slope distribution goes through a region of maximum non-gaussian shape and then becomes more nearly gaussian again as the wind velocity increases. In this general region it becomes evident that water droplets are starting to be drawn into the air near the water surface. It may be possible that this phenomenon may tend to make the slope distributions more nearly gaussian for the higher wind velocities. It is also interesting to note that this is the same region of wind velocities as that in which *Mandelbaum* [1956] found evidence of a critical wind velocity for air-sea boundary processes.

Figure 5 is included to show the actual wave slope distribution for a 20-kn wind together with two gaussian approximation distributions having the same areas under the curves. The general shapes of the solid and the dotted curves are very similar to the one presented by Cox and Munk when it is remembered that the negative-positive wave-slope convention is reversed. The dashed curve in Figure 5 was included to show that the gaussian approximation fits the actual distribution better if it is centered around the mode rather than the zero-slope line in this particular case.

Sources of error—Several things have contributed errors in the data. The probe for the air velocity meter was about two inches from the water sur-

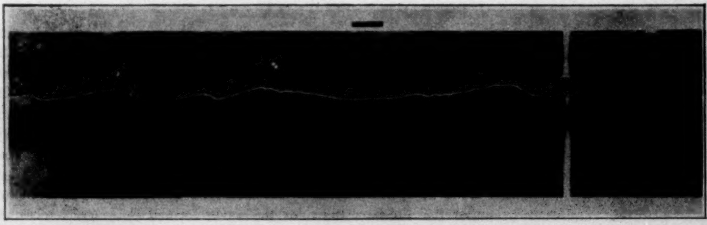

FIG. 2 – Wave profile with 16 kn wind

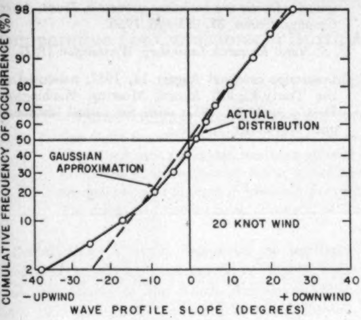

FIG. 3 - Linear probability paper plot

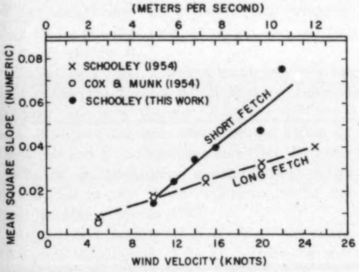

FIG. 4 - Mean square slope vs. wind velocity

face, and at the higher wind velocities there was a tendency for its calibration to be affected by water spray. Care was taken to check the accuracy of the instrument against two other instruments in an air stream outside the wind tunnel. Experimental errors caused by imperfect wave absorption at the end of the channel are also probably present. The difficulty of obtaining good absorption increases as the wind velocity is increased. Limited experiments were made for optimizing the slope of the screen beach to reduce reflection. Other less successful absorbers were also tried.

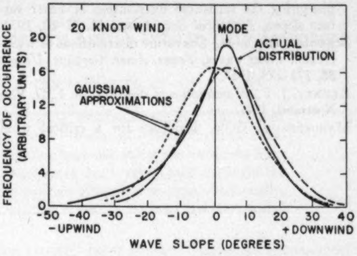

FIG. 5 - Wave slope distribution curves

TABLE 1 - *Mean, median, and mode of actual distributions for various wind velocities*

Knots	Degrees slope			Distribution peaked
Wind velocity	Mean	Median	Mode	
10	−1.0	0.2	2.6	Yes
12	−0.1	2.5	7.7	Yes
14	0.4	1.9	4.9	Yes
16	1.2	4.0	9.6	No
20	1.1	2.2	4.4	Yes
22	0.6	1.5	3.3	No

The accuracy of the lucite-water-air intersection as representative of the water surface contour is not known quantitatively. Inspection of the pictures indicates that it is fairly satisfactory as a first approximation. In experiments of this kind there is concern as to whether the statistical samples are large enough and are representative. The sampling used was based principally on the desire to get a reasonable amount of results in reasonable time. Even so, the original wave-profile pictures were taken in 1953. It is regretted that photographic difficulties made the picture for 18 kn unusable, and hence there is a gap in the data at a very interesting point.

Conclusions—Under the conditions in which the data were taken and analyzed it may be concluded that for 15-inch fetch water waves:

(1) The mean-square slope is greater than for fetches of more than 1000 ft. At 16-kn wind velocity the mean-square slope is 70 pct greater.

(2) The actual distributions of wave slope for various wind velocities appear to be peaked and to be skewed in the downwind direction.

(3) The amount of peakedness and skewness reached a maximum in the region between 16 and 20 kn.

Comparative Ice Conditions in North American Arctic, 1953 to 1955, Inclusive

JOHN J. SCHULE, JR., AND WALTER I. WITTMANN

Abstract—Regularly and systematically conducted aerial reconnaissance is at the present time replacing ship and shore observation as the primary means of collecting sea-ice data. Since 1953 new knowledge has been gleaned concerning seasonal variations occurring deep within the outer confines of North American pack-ice areas. Ice breakup and disintegration are now believed to begin in icebound, far northerly regions. These regions expand seasonally. The origin and development of several of these 'centers of sea-ice removal' are discussed.

Introduction—A rapid expansion of regularly scheduled aerial ice reconnaissance flights over seas and oceans of the North American Arctic since 1953 has added immeasurably to our knowledge and understanding of ice conditions there. In addition, it has provided additional knowledge of and insight into the environmental processes that are the result of ice distribution and, in some cases, determine it.

Except for a brief, intensive excursion into the field during the Second World War by German military scientists [*German Hydrographic Institute*, 1950] and for brief and sporadic flights by Canadian and U. S. agencies since that time, virtually no comprehensive understanding of ice distribution in the North American Arctic has been possible prior to 1953.

As described recently [*U. S. Hydrographic Office*, 1956], the ice program of the U. S. Navy Hydrographic Office became firmly established in 1953. The result has been a much more synoptic and inclusive understanding of daily, weekly, monthly, and annual variations of ice conditions within Arctic sea areas than had previously been possible. Through comprehensive aerial ice reconnaissance and the use of standardized ice observational procedures, extensive knowledge can now be gleaned of periodic variations of sea ice conditions such as boundaries between ice and water, concentrations within the ice, age and thickness of the ice, the degree of ice deformation, and the stage of ice disintegration.

Data, of course, are still insufficient for the determination of an accurate and complete concept of 'normal' ice conditions, such as might be necessary for a complete revision of a publication such as H.O. Pub. No. 550 [*U. S. Hydrographic Office*, 1946a]. However, several important new concepts have emerged from the data acquired in the three years 1953 to 1955. Several historical notions derived as a result of older ice information, gained largely through sporadic and widely scattered ship ice reports, have proven themselves inconsistent with the newly obtained information. This new information, and not the older concepts, will form the basis for the following discussion.

Types of ice and ice packs—Figure 1 depicts the probable average maximum extent of sea ice throughout the entire year (slant hatching). Most of this ice is commonly known as 'polar ice,' or ice which survives the short thawing season each year and in some cases may be the source region for hard and heavily ridged and hummocked ice that drifts southward. On the other hand, a quite different type of ice is that characteristically present in the Baffin Bay-Labrador Sea area, in the southwestern Canadian archipelago and in the Bering Sea. It forms and is completely disintegrated within a single season. Such ice is commonly called 'winter ice,' or ice of one year's growth, and is most prevalent in the areas represented by the dotted hatching in Figure 1.

Furthermore, two types of Arctic ice pack must be distinguished. The first is a stream of mobile ice drifting southward to its eventual destruction; the second may be thought of as a quasi-stationary pack or one more or less confined to its region of origin throughout its life span.

The East Greenland coastal ice is the most dramatic of the drift-stream type. Its minimum coverage extends to the vicinity of Scoresby Sund or approximately 70°N, in October. Its maximum extent occurs in June. At this time it is in the form of a continuous drift having its origin in a trajectory across the entire Arctic Ocean over the north geographical pole, from whence it moves southward to Kap Farvel, rounding the cape and continuing northwestward to approximately 61°N. This ice stream has been found to be characterized by an extremely marked short-term variation in extent and concentration. Indeed, central portions of the stream are sometimes entirely cut off, owing to variation in the wind-induced components of current and ice drift. At times within the naviga-

FIG. 1 – Seasonal expansion in the coverage of sea ice, 1953–1955

tion season, for example, ships may close the coast at ports in the vicinity of the 65th parallel, whereas obstreperous ice is, at the same time, raising havoc with shipping attempting to reach the USAF base, situated at BW-1, much farther southward at approximately 60°N.

A unique characteristic of the East Greenland coastal ice is its complex composition. In the period between June and October and in the region between Iceland and the southern tip of Greenland, three primary types of ice occur. Most prevalent is polar ice of several seasons' growth that is being transported southward to its eventual destruction. Considerable quantities of winter ice formed to the north are also included. Along the immediate coastline, a great deal of fast ice formed in the inland fiords is supplied by the strong and frequent foehn winds, blowing eastward off the Greenland ice cap.

The Baffin Bay pack is an example of the type largely confined to its region of formation, and contrary to prior belief [*Weaver*, 1951], it begins to form in late October or early November. It attains total coverage by approximately January 15 and has totally melted by approximately August 15. Although conditions vary greatly during the navigable season, the new data indicate that more mobile ice containing greater quantities of ridged and hummocked ice and to a lesser extent old hard polar floes are more predominant on the Baffin Island side then elsewhere. The historical notion of the 'middle pack' [*U. S. Hydrographic Office*, 1946a] seems doubtful. The last ice to disintegrate is apparently not the ice of the central bay but the ice moving southward along the western shores of Baffin Bay. This ice is partly of polar origin, containing floes from the Kane Basin and Lancaster Sound source regions.

The Labrador ice stream, although considerably less formidable in thickness and inaccessibility to shipping, contains quantities of sea ice contributed from both the Baffin Island coast and, late in the season, from Ungava Bay and Hudson Strait. Along the Labrador coast especially it has been found that persistent ice and 'severe' ice seasons are the result much more of environmental conditions in the source regions to the north than of those over the area in the immediate vicinity of the ports and harbors affected. Ice drift here, however, is also extremely responsive to such local factors as storms, currents, and winds. Coastal harbors here have an extremely serious ice problem owing to the effects of these factors in combination with tidal forces and bathymetry. As a result, marked diurnal variations sometimes occur in the case of accessibility to harbors along the northeastern coast of Labrador.

In any of the areas shown in Figure 1, it has been noted that a severe June is frequently followed by a mild or light July. Exactly the converse is often true, as was especially evident in the approaches to Frobisher Bay during the 1953 ice season.

In Foxe Basin the notion of a self-contained cyclonic ice circulation held by such pioneering explorers as Bob Bartlett, [*U. S. Hydrographic Office*, 1946b] is believed on the basis of more recent information to be only partially true. The cyclonic circulation seems to prevail only in the northern portion of the Basin. It is believed that in the southern portion of Foxe Basin much of the ice sets southward and southeastward, affecting the clearing of ice from Hudson Strait.

In 1955, excellent comprehensive reconnaissance data indicated that by late September only a minute quantity (approximately 3 pct) of the ice survived the season in Foxe Basin and was available for later classification as polar ice. The predominant polar ice historically attributed to this region is probably present only in unusual years. Rather, persistence of ice in this region appears to be more the result of the interaction of extreme and radical variations in the direction of wind stress on the ice, shallow bathymetry, and an almost completely surrounding coastline. These factors create in Foxe Basin the most severely ridged and hummocked ice found throughout the polar regions of North America, except for the regions just to the north of Greenland and Ellesmere Island. Another erroneous notion sometimes evident in Arctic literature is that the ice in the northern part of Foxe Basin is more concentrated and persistent than that in the central or southern portions. The converse has definitely been observed during the seasons here reported.

In the water area between Amundsen Gulf and Shepherd Bay, total ice coverage is attained by late November, and it is believed that in most seasons the ice is completely disintegrated in the period between August 15 and September 15. Exceptions to this rule occur in persistent strings of remnant pressure ridges found in the eastern portions of this region. Here, as in other areas discussed, extreme variability occurs both within the season and regionally as a result of drift situations induced by storms, winds, and other environmental factors. Particularly at both extremities of the region, early clearing in the navigation season may lead to unjustifiable complacency, as when heavy ice forced its way southward through Victoria Strait (to the southeast of Victoria Island) in August 1955, and also when the polar pack intruded upon the coast between Barter Island and Cape Bathurst during early September 1953.

Understanding of ice conditions deep within the polar pack between the meridians of the Bering Sea and Cape Bathurst is at this time incomplete. This is true not only because of the sparse environmental data which exist over the oceanic area north of the Alaskan coast, but equally because of the wide spacing in the network of meteorological stations fringing that area. However, every year the additional scientific information gained from ice reconnaissance and drifting ice stations makes the potential of accurate forecasting here even greater than in the more complicated, shallow, and enclosed areas previously described. The new data, for example, indicate that the line depicting the probable minimum ice coverage in the North American Arctic (heavy dotted line in Fig. 1) dips deeply southward into the Canadian Archipelago between Prince of Wales and Victoria Islands. Ice measurements made at the Canadian-U. S. Joint Weather Stations since their establishment in the period 1946–1949 agree with the aerial reconnaissance data in placing this line farther south than either Russian ice charts [*U.S.S.R.*, 1953] or the *Ice Atlas of the Northern Hemisphere* [*U. S. Hydrographic Office*, 1946a] would lead one to believe. Both atlases indicate the polar ice line as lying entirely seaward of the Greenland-Canadian Archipelago.

The Bering-Chukchi pack ice attains its maximum coverage in early March and is usually totally open in early July. Although somewhat lighter, it closely resembles the pack ice of Baffin Bay in that a quasi-stationary ice mass exists which disintegrates largely in situ.

Certain scientific approaches concerning the ability to predict within-season variability in pack ice conditions are becoming possible as a result of comprehensive ice reconnaissance. Predominant among these is a more accurate determination of the relationship between the velocity of ice drift and wind velocities. In addition, the relationships that exist between varying combinations of environmental parameters are becoming better known. Some of these relationships are the amount of ice disintegration and pressure ice that occurs through an 'ice season,' the thinning out or consolidation of pack ice that occurs owing to the components of vorticity of the wind stress on the ice, and the effect of these factors on incipient ice destruction or disintegration. Work on this later problem is proceeding at the present time. Especially significant is the work started at the Hydrographic Office in relating the local time-rate of change of ice concentration to the vorticity of the wind stress, to the advection of ice, and to the change in ice concentration that results from melting or freezing.

Annual variability in the Arctic pack ice—Perhaps the most spectacular information gleaned through ice reconnaissance during the past three years has concerned the extreme variations in ice distribution that occur from one season to the next. Figure 2 clearly illustrates this point. In 1955 during the navigation season in mid-July the Baffin pack was entirely confined to the Baffin Island area, and its extension in the Labrador ice stream extended farther south than was the case in the previous two seasons. The Thule approaches in the region of 75°N at the same time were completely devoid of ice, unlike the previous two years. Although initial convoys into Thule sighted no sea ice in 1955, at the same time in 1954 two heavy Wind-class icebreakers were battling difficult ice conditions in bringing the first ship into Thule. These facts clearly indicate the danger of generalizing, from individual ship experiences, on the severity of the ice season over a wide area. Scientific correlations based on ice charts compiled from sporadic ship reports are therefore of extremely doubtful validity. Ships supplying the Labrador coast in 1955, for example, would have reported a severe ice year for the entire eastern Arctic. Ships similarly supporting Thule would have reported the converse.

The same dramatic differences in year-to-year ice conditions are evident in Figure 3, on the Alaskan side. In 1954 icebreakers were able to circumnavigate Banks Island, with little difficulty. In both 1953 and 1955, on the other hand, ice conditions in this same area were extremely difficult, and a similar operation was inconceivable. In 1953 the difficulties in early September were largely confined to the eastern portions of the north Alaskan coast, whereas in 1955 persistent on-shore drift and mass movement of the polar pack were much more obvious in the western portions of the area. Early indications for conditions such as those encountered in 1954 were reflected in computations of theoretical ice drift made for the formative ice development period from Sep-

tember 1953 to April 1954. Theoretical drift during this period reflected an extremely strong, east-to-west movement of 2½ to 3½ nautical mi/day. The extreme southern portion of the Arctic pack at this time was characterized by increasing ice drift velocities from east to west in the region north of Point Barrow, naturally reflecting a thinning out or divergence of the polar ice. The ensuing light ice experienced west of Banks Island and the extreme northerly position of the ice

boundary off Point Barrow (Fig. 3), were probably in large part determined by the anomalous drift situation described.

Figure 4, showing the area of ice present in the Baffin Bay-Davis Strait area for the breakup period of 1953–1956, emphasizes that internal differences of ice distribution are most responsible for an ensuing light or heavy ice year in a particular area. It can be seen from this figure that the total production of ice in each year, 1953–1955, is approximately constant; yet the great annual and areal differences in navigable conditions already described occurred despite this constancy.

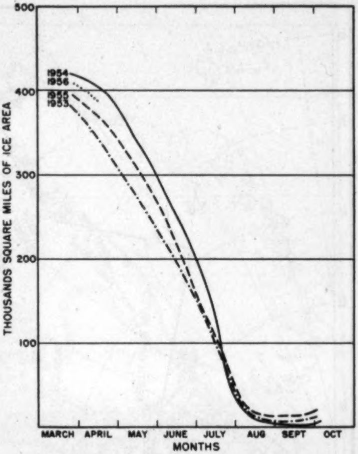

FIG. 4 – Seasonal expansion in the estimated quantity of ice in the North American Arctic, 1953–1956, inclusive

Centers of sea-ice removal and disintegration—Perhaps the most important contribution of ice reconnaissance to sea-ice forecasting is the significant additional knowledge gained of certain peculiar areas of weakness within the pack ice. Figure 5 depicts six regions where open, partially open, or very unstable ice predominates, despite air temperatures in these regions having averaged below −25°F for two or three months prior to their existence. Disintegration and removal of ice proceed outward from these areas during the breakup season. A few of the areas will be discussed briefly in the paragraphs below. Schematic charts showing the general seasonal expansion of these centers of sea removal for the Eastern and Western portions of the North American Arctic are shown in Figures 6 and 7, respectively.

The North Open Water is probably the most classical of these regions. Its existence has been known for hundreds of years, and it was exploited by the whaling expeditions of the 17th through the 19th centuries. The older explanation for this occurrence has been the sinking of the West Greenland Current as it crosses the submerged ridge across Davis Strait following along the coast of Greenland, and its reappearance, with consequent upwelling, as it rises again along the ridge of northern Smith Sound [*Killerich*, 1933]. Recent information suggests a more credible explanation to be a back-logging and jamming of ice moving generally southward across the geographic bottleneck of northern Smith Sound. Persistent, frequent, and strong northerly winds jam the ice in this area, causing separation and continuous removal of ice south of the jam. Each year at the culmination of the Arctic winter, in early March, the line of polar ice across the northern sound is very clearly in evidence curving northward in an architectural form similar to a naturally built stone or steel arch bridge. For the past three years the extent of this North Open Water has for the first time been accurately surveyed throughout the navigation season.

The ice jamming and strong wind factors are probably also largely responsible for the Barrow Strait Polynya and the Igloolik Lead. The Big Island Lead, on the other hand, is more attributable to natural current divergence combined with persistent, strong off-shore winds. The Bathurst Polynya apparently has still other explanations: here strong rip currents flowing back and forth across a submerged ridge apparently result in vertical eddies which keep the water well mixed and supply a constant replacement of relatively warm surface water. A further explanation for the Bathurst Polynya is the probable existence of a permanent southwesterly setting current across the western entrance of Amundsen Gulf. Open water and unstable ice result as the current continuously removes ice from the consolidated ice cover of inner Amundsen Gulf.

The Chukchi Lead is probably the result of a surface reappearance of the Bering Sea Current, which flows weakly through Bering Strait to the northward. It widens or narrows markedly, however, with changes in the offshore and onshore components of ice drift.

The centers located in the eastern North American Arctic make their first appearance in late March (Fig. 6). At this time the North Open Water is defined at its northward limit by the boundary between the polar ice northward of Smith Sound, to the westward by the fast frozen ice of Jones and Lancaster Sounds, to the eastward by the fast bay ice of the coastal indentations of western Greenland, and to the south by the solid pack ice cover of Baffin Bay. FIG. 7 – Seasonal expansion of centers of sea ice removal in the North American Arctic: western portion

Open Water area is almost completely devoid of all sea ice, and evidences of breakup and lesser concentrations are present to the southeast and southwest.

The Barrow Strait Polynya in late March is pre-evidenced by two broken ice areas, one just north of Somerset Island and one just west of Resolute. By mid-June, it has spread eastward into Lancaster Sound, and is completely open.

Poor flying weather precluded knowledge of the ice conditions in the northern Foxe Basin during March 1955. However, an 8/10 concentration of ice in the form of small and medium floes and even smaller ice size types was observed in the northwest basin. On the other hand, progressively larger concentrations occurred to the south (9/10 and 10/10). By mid-June definite openings were evident in the vicinity of Igloolik. One of the authors, accompanying the initial ice reconnaissance flight over the area, personally observed in March of 1956 an 18- by 100-mi area containing only such unstable ice types as windrowed slush and young ice in the northwestern extremities of Foxe Basin. This area persisted in spite of low surface air temperatures in sharp contrast to the virtually solid, heavily hummocked ice over the entire remaining portion of the Basin southward of Foxe Channel.

In mid-March the Big Island Lead (Fig. 6) usually exists as a narrow coastal strip stretching southeastward from that island. Less than 1/10 ice cover characterizes the lead. By mid-June a rapid widening develops southward of Big Island; by mid-July the expansion includes the greater part of central Hudson Strait.

By late July the Barrow Strait Polynya has merged with the North Open Water and both have become contiguous with the open waters of the West Greenland Current and the Labrador Sea. The Big Island Lead now encompasses the greater central portion of Hudson Strait. By mid-August, all three centers of sea ice removal have lost their separate identity as Baffin Bay, the Labrador Sea, and Hudson Strait have become completely free of sea ice.

The rugged, hummocked ice in Foxe Basin behaves quite differently. In late July only the area near Igloolik in the northwest shows marked diminution in ice cover. Not until after mid-July does the area of less than 1/10 ice cover spread rapidly to the south and southeastward. Toward late September the Basin experiences its seasonal ice minimum, despite the fact that new ice occasionally starts or has already started to form. It should be stressed that aerial reconnaissance throughout the Arctic has emphasized the wide overlap, four to six weeks or more, between the last stages of the disintegration process and the time of widespread new ice formation.

The expansion of open water from areas deep within the Arctic pack ice is just as spectacular in the western portion of the North American Arctic (Fig. 7) as it is in the eastern. The Bathurst Polynya, south of Banks Island, shows a continuous expansion after late April, especially ~~in the~~ mid-June through mid-August period. The Chukchi Lead, too, shows continuous expansion, although in the Point Barrow vicinity congestion frequently occurs throughout the period from mid-July to mid-September. Worsening in this manner occurs as the more mobile pack ice of the late summer can and does respond to the predominant direction of ice drift in any particular period under consideration. Strong southerly and southwesterly sets in the ice drift during August 1955 resulted in the difficult ice season experienced.

All composite seasonal ice charts compiled at the Hydrographic Office since 1953 support the arguments of ice breakup occurring outward from the centers of sea ice disintegration. Also, the new data for 1956 reveal all the centers mentioned as areas of thinner and less concentrated ice.

Conclusion—In just a few years, comparative study of aerial ice reconnaissance information has greatly increased our knowledge of ice distribution in the North American Arctic. Such data strongly indicate that annual variability in ice distribution and the location of ice boundaries is probably due in large part to year-to-year variations in the drift and movement of ice rather than to variations in the quantity of ice produced. Within each season, too, considerable variability occurs in ice coverage, following a complex but usually recurring pattern. The primary feature of ice disintegration in the Arctic is not an orderly and gradual northward recession of pack boundaries during the summer months, but rather a steady outward progression from several well defined areas of weakness in the various sea ice regions.

Time of Flow Studies, Ottawa River, Lima, Ohio

CONRAD P. STRAUB, F. J. LUDZACK, G. R. HAGEE, AND A. S. GOLDIN

Abstract—Chemical (sodium chloride), colorimetric (fluorescein dye), and radioactive (rubidium^{86}) tracer techniques were used to measure the time of flow of the Ottawa River below Lima, Ohio. Two runs were made during a two-week period in August 1956, when low stream conditions prevailed. In the first run fluorescein dye and rubidium tracer were introduced into the stream and measured at two stations located 1.0 and 1.9 miles downstream, and in the second, dye and radioactive tracers, and sodium chloride were introduced and measured at three stations located 1.0, 1.9, and 4.5 miles downstream. The results show that under existing test conditions all tracers gave similar results and the maximum deviation was generally less than ten per cent. The equipment and facilities needed to carry out the field and laboratory tests are described and the costs and limitations of each method are indicated.

The use of radioactive tracers for determining flow time and dispersion in water courses has been known to hydraulic and sanitary engineers for some time. *Joly* [1922] proposed the use of radium for this purpose, and suggested an acid pitchblende solution (containing radium) be introduced into a stream and that the evolved radon be measured by an electroscope. *Hess* [1943] reported the use of radium as a tracer for flow measurements in tank experiments. A variety of reactor-produced radioisotopes have been used in hydraulic studies in the last decade and include sodium^{24} [*Karrer* and others, 1946; *Knop*, 1951; *Putnam* and *Jefferson*, 1956], potassium^{42} *Seaman* [1956], iodine^{131} [*Archibald*, 1950; *Thomas* and *Archibald*, 1952; *Straub* and *Hagee*, 1957; *Tsivoglou* and others, 1956], phosphorus^{32} [*Parker*, 1955; *Thomas*, 1956ab], bromine^{82} [*Straub* and *Hagee*, 1957; *Sons*, 1952; *Montens*, 1952, 1955], rubidium^{86} [*Straub* and *Hagee*, 1957; *Fox*, 1952; *Ambrose* and others, 1957; *Truesdale*, 1953], cobalt^{60} [*Anonymous*, 1953], scandium^{46} [*Putnam* and *Jefferson*, 1956; *Ely*, 1957], radium [*Bullen*, 1954a], and radon [*Bullen*, 1954b]. These isotopes were used to determine flow time and dispersion in pipes, settling basins, detention tanks, natural lakes and ponds, oxidation ponds, and ground waters.

In the past engineers have relied upon salt and dye tracers for an evaluation of flow time and dispersion, or have depended upon the use of floats or cross sectioning. These methods have certain drawbacks, and the use of radioisotopes offers some hope for a better method of determining these parameters.

In connection with studies that were being carried out by the Robert A. Taft Sanitary Engineering Center on the behavior of oils in the Ottawa River near Lima, Ohio, information was desired on the time of travel of the effluents from an activated sludge sewage treatment plant and a refinery. To obtain this information, time of flow studies were carried out using chemical (sodium chloride), colorimetric (fluorescein dye), and radioactive (rubidium^{86}) tracer techniques. Two runs were made during a two-week period in August, 1956, under low stream flow conditions.

Field operations—For the first run, 1.5 lb of fluorescein dye and 265 millicuries (mc) of rubidium^{86} tracer were added to the Ottawa River at the sewage treatment plant outfall. At each of two stations, located 1.0 (Sta. A) and 1.9 (Sta. B) miles below the point of introduction of the tracers, one-quart samples were collected at the mid and quarter points of the stream. Duplicate 100-ml portions were taken for laboratory counting and for determination of the fluorescein concentration. The temperature of the residual sample was recorded and the activity level was measured on a survey meter (Model MX5 survey meter, Beckman Instrument Co., Richmond, California) and a field scaler unit (Model 80 Field Scaler, Berkeley Division, Beckman Instrument Co., Richmond, California), each of which was equipped with a rubber-encased G-M probe. A notation was also made as to whether the dye concentration was higher or lower than that of the preceding sample.

In the second run, made a week later, the amount of fluorescein was increased to six pounds, since weak color and erratic results had been obtained in the initial run. The dye, along with 300 mc of rubidium^{86}, was added at the sewage treatment plant outfall. At a point approximately 0.1 mile upstream, 3000 lb of sodium chloride were also released.

Since the field scaler measurements gave useful data in the first run this unit was selected to give a continuous record of the activity levels (integrated) passing Station A. Unfortunately, the instrument failed just at the time that activity reached this station. Samples were collected as in Run 1, but no field measurements were made, all samples being analyzed in the laboratory. Because of the increased concentration it was possible to follow the dye for a greater distance and samples were collected at a third station (Sta. C) located approximately 4.5 miles below the sewage treatment plant outfall. Visual observation showed good dye color in the river the following day at a station 7.8 miles below the point of introduction.

Laboratory measurements—For the determination of radioactivity a sample of 10 ml was placed in an aluminum dish, evaporated to dryness, and counted in an internal proportional counter (Model PC-1, Nuclear Measurements Corp., Indianapolis, Indiana.).

The fluorescein dye concentration was estimated on a Beckman Model B spectrophotometer, from the absorbance of fluorescein at a wave length of 490 millimicrons (mμ) in a 5-cm cell. The refinery waste materials had negligible absorbance at this wave length while fluorescein absorbance was high. Measurements of the dye by fluorescence was not possible because of the variable fluorescence of the refinery effluent. Settled samples were read against a blank of Ottawa River water taken prior to the arrival of the dye. Fluorescein, in concentrations of 40 to 1000 μg/l, gave absorbance readings ranging from 0.05 to 0.70 with a reproducibility of five per cent.

The Mohr method was used to estimate chloride concentrations [*American Public Health Assn.*, 1955]. Settled river-water samples were titrated after pH adjustments only. Sample volume varied from 25 to 100 ml depending on chloride levels. The titration error was relatively independent of sample size, hence high concentrations were subject to more absolute error. Reproducibility in titration of duplicate samples was within 0.3 mg, hence the variation on a 100-ml sample was less than 3 mg/l; on a 25-ml sample 12 mg/l. The presence of a slight oily film on the river precluded the use of a conductance cell for chloride estimation. The refinery and petrochemical plant cooperated in holding salt brine discharges from process operation to minimal amounts to avoid rapid fluctuations in river chlorides during the sampling period.

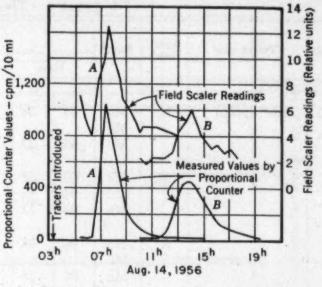

FIG. 1 – Ottawa River, time of flow using radioactive rubidium tracer; first run, August 14, 1956

Results—The results obtained in the first run were plotted as indicated in Figure 1 and summarized in Table 1. With a stream flow of approximately 23 – 26 cfs, the modal time of travel for the mid-stream samples was 3.97 hr from the sewage treatment plant outfall to Station A (1.0 mi downstream) and 10.38 hr to Station B (1.9 mi downstream) based on laboratory radioactivity measurements; 4.13 hr and 10.63 hr, respectively, based on field radioactivity data. The mean flow times (laboratory data) to Stations A and B amounted to 4.53 hr and 10.93 hr, respectively. Data obtained with the field survey meter or with the dye tracer were unsatisfactory.

The results of the second run (stream flow approximately 19 – 21 cfs) are plotted in Figure 2 and summarized in Table 1. On the basis of the mid-stream sample data, the modal times of travel to Stations A, B, and C were 4.25 hr, 10.25 hr, and 21.5 hr using rubidium^{86}; 4.0 hr, 9.7 hr, and 21.5 hr using fluorescein; and 5.3 hr, 10.9 hr, and 22.0 hr using sodium chloride, respectively. The sodium chloride was introduced 0.1 mi upstream of the other two tracers and the time required for it to reach the downstream stations would therefore be expected to be somewhat greater than is the case for the other tracers. Float studies for this 0.1-mile section indicated a median and mean range time of 35 min. The mean values are listed in Table 1 along with modal and median values.

The results with the various tracers may be compared through a consideration of the time required to flow from Station A to Station B, Station A to C, and Station B to C. From an examination of the data in Table 1, it will be seen that the midstream modal value for time of travel be-

[c] T_{O-A}, T_{O-B}, etc., time interval required for flow from point of introduction to Station A, point of introduction to Station B, etc.

tween these stations amounted to 6.0, 17.25, and 11.25 hr with rubidium[86]; 5.7, 17.5, and 11.8 hr with fluorescein; and 5.4, 16.7, and 11.1 hr with sodium chloride, respectively. The elapsed time based on the mean values did not differ greatly from the modal values.

In Table 2, the deviations based upon the midstream modal and mean values are shown, and

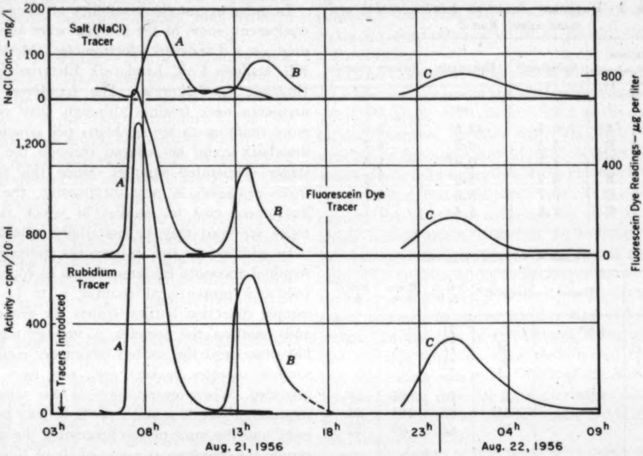

FIG. 2 – **Ottawa River, time of flow using radioactive rubidium, fluorescein dye, and sodium chloride salt tracers; second run, August 21–22, 1956**

it will be noted that the maximum variation amounted to four per cent. The maximum deviations between modal and mean values without regard to location across the stream are summarized in Table 3. Note that the maximum deviations occurred in the initial stretch of the stream from point of introduction to Station A, and that in general smaller differences were noted in the case of the rubidium tracer than the other tracers.

Along with the tracers used herein, on two occasions floats (oranges) were placed in the stream to determine the time of flow between stations. Several dozen oranges were dumped in all, but none were recovered at any of the sampling stations excepting the 0.1-mile section described where floats were constantly attended. They were found lodged in debris along the banks of the stream not far from their point of release.

In Table 4, the actual recovery of each tracer at the downstream stations (B and C) is indicated as a percentage of the amount of tracer passing Station A. Recovery of rubidium was appreciably higher than that for the other tracers. The average rubidium recovery between Stations A and B was 74 pct in the first run, and 65 pct in the second, with no additional loss between Stations B and C. In Run 2, dye recovery at Station B averaged 65 pct of the value at Station A. Thirty-five per cent of the dye was lost between Stations B and C, making the overall recovery 42 pct. Slightly less than 60 pct of the salt passing Station A was recovered at Station B with no further loss of salt in moving to Station C.

Equipment needs for radioactive tracers—Several types of instrumentation may be used in counting radioactive samples, depending in part on the tracer radioisotope used. In this study, as was in-

dicated earlier, field instruments were tried, and it was found that the Berkeley Field Scaler could be used with a rubber-encased probe. A survey meter attached to a rubber-encased probe did not give sufficient sensitivity. Satisfactory laboratory-type instruments include any of the available conventional instruments such as the G-M end-window counter, the internal gas proportional counter, or where a gamma-emitting isotope is used, a scintillation counter. The latter type of instrumentation has the additional advantage that processing of the sample prior to counting is avoided. In the case of the end-window and proportional counters, such processing is prerequisite. Another disadvantage of the use of the internal gas proportional counter, particularly if taken out into the field, is that a source of counter gas is needed, which means additional equipment to be transported. The internal proportional counter, however, because of its high counting efficiency, gives high sensitivity without inordinately long counting times. In addition it enables the activity to be followed over larger dilutions.

In order to test the possibility of using simpler equipment, some of the samples were also measured on a Landsverk electrometer (Model L-75 KB Analysis Unit, Landsverk Electrometer Co., Glendale 4, California). The Landsverk measurements were feasible although they required more time; up to several hours per sample. This drawback could be reduced through the use of larger evaporated samples. Since this type of instrumentation is very inexpensive, the initial instrument cost for studies in which radioisotopes are used may be materially reduced.

In addition to the instruments indicated, the required accessory equipment such as counter gas (where a proportional counter is to be used), sample collection bottles, dishes for evaporating and counting the samples, a voltage regulator, hot plate, and the normal laboratory equipment such as pipettes, beakers, etc., will have to be provided. Where evaporation of the samples is required, about 30 samples per hour may be processed and the same person processing the samples can do the counting, at a rate of about 10 samples per hour on a single instrument.

Equipment needed for fluorescein determinations—For this purpose a Model B, Beckman spectrophotometer was used. It is quite obvious that this type of instrumentation like the G-M end-window counter, the internal gas proportional counter, or the scintillation counter, cannot be used directly in the field, but may be set up in a temporary laboratory with suitable line voltage. It may be possible to get some concept of fluorescein concentrations through the use of calibrated Nessler-type tubes. Sensitivity may be low, but it may be possible to get some idea of when the peak concentration passes the sampling point and when sampling can be stopped.

Samples may be run without any processing, except sedimentation. About 10 to 15 samples may be run per man hour. Ordinary laboratory glassware may be used. Dye tracing has certain obvious advantages in that rough estimates with visual observations only are possible. Time of passage, current characteristics, and sampling for other tracers can be controlled more readily in its presence.

Equipment for chloride determinations—No special equipment is necessary in running chlorides. If desired, analyses may be made in the field, but it is more convenient to carry them out in the laboratory. About 10 to 12 samples may be titrated per man hour if single analyses are made per sample. This number will be cut in half if duplicate samples are analyzed. The equipment needed includes burettes, beakers, and standard solutions.

Costs and limitations—Where instrumentation is available for making the determinations indicated, the principal costs will be for the procurement of the specific tracers used, and in the man hours required to collect the samples and to process them. As indicated above, the amount of time needed to process the samples is about the same in each instance. Processing will be required in the case of samples counted for radioactivity and for chloride determinations; none being required for processing the fluorescein samples. No processing would be required for a gamma-emitting radioisotope counted with a gamma scintillation counter.

In our case, the cost of procuring the needed tracers amounted to approximately $60 for 300 mc of rubidium^{86}, $50 for six pounds of fluorescein, and $40 for 3000 pounds of sodium chloride exclusive of handling. If the basic instrumentation needed for making such a study is not available about $1000 will be needed to purchase an internal gas flow proportional counter and about $200 to $300 for other accessories. A Beckman Model B spectrophotometer would cost approximately $500 if one is not available. No other equipment will be needed to determine fluorescein concentrations. In the case of chloride determinations, no specialized equipment is needed. If one wished to monitor or make chloride determinations directly in the field, it would be possible to do so using a conductivity cell, but there are certain limitations on the use of this equipment. It could not be used in this case because of the presence of an oily film on the surface of the stream.

One limitation on the use of radioactive materials as tracers is that they be compatible with the water under test. One would not want to use a radioisotope that is quickly precipitated, adsorbed, or metabolized. To minimize adsorption or metabolism of the radioisotope an isotopic or chemically related carrier is added. Since the radioisotope itself is used in such small concentrations on a weight basis, there is no danger of materially affecting the specific gravity of the solution under study as may happen with sodium chloride or other added salts. Furthermore, color which interferes with the use of dye tracer does not affect the use of a radioisotope. Turbidity influences the use of fluorescein and radioisotopes, particularly if the radioisotope is readily adsorbed. As stated above, to counteract this adverse effect, one would add carrier to the radioisotope. In the fluorescein samples it was found that the addition of alumina cream for clarification resulted in variable losses of fluorescein.

Sodium chloride or other similar salts would be unsatisfactory for use in streams having a variable chloride content. Also any ions, such as the other halides, cyanides, or other materials, that react with silver ion could not be used because they would give a false indication of the chloride levels in the stream. Since the titration involves a color change, the technique could not be used with a highly colored waste or stream. In addition, the increase in specific gravity that would occur might result in a layering of the added tracer and a false indication of flow time. This would be particularly true if one were measuring the flow time of a deep stream. In the case of the Ottawa River which had variable stretches, some shallow and ripply and other deep ponds, the effect of the variable specific gravity may not have exerted as marked an influence as it would in the case of a slow moving rather deep stream.

Mixing of NaCl in the stream is a critical factor in the use of this as a tracer. During this study, a saturated brine solution was added to the flow in the refinery outfall channel. A high velocity, a Parshall flume, a two-foot cascade, and about 50 ft of riffled area should have accomplished good mixing. However, mixing was not complete, as the chloride concentrations in a pool of about 2½ ft depth immediately below the riffled area showed concentrations more than twice as high at the 25-inch depth as at the 2-inch depth even after more than seven hours after introduction. As shown in the results, this factor contributed to a somewhat longer passage time to and poor recovery at the first sampling station. Good recovery and consistent behavior were evident at subsequent stations.

Acknowledgment—The authors express their appreciation to Gerald Karches and Robert N. Bloomhuff of the Robert A. Taft Sanitary Engineering Center for their assistance in collecting and processing the samples. Acknowledgment is also made of the use of the laboratory facilities at the Lima Sewage Treatment Plant.

Radiotracer Experiments in the Mohawk River, New York, to Study Sewage Path and Dilution

E. S. SIMPSON, W. A. BEETEM, AND F. H. RUGGLES

Abstract—Sewage from the Knolls Atomic Power Laboratory near Schenectady, N. Y., was dosed with 4.53 curies of P^{32} prior to discharge into the Mohawk River. Its pattern of diffusion was measured in the river with immersible GM-tubes and by sampling. The initial path of sewage was strongly influenced by differences in density between sewage and river due to temperature. During warm months relatively cold sewage moved on the river bottom perpendicularly to river current. For at least the first 800 ft of travel the maximum sewage concentration decreased logarithmically with distance from outfall. The term 'half-distance' (here about 110 ft) is proposed to describe the concentration change. During cold months sewage rose to the river surface and at times was moved upstream by wind. However, when the river temperature was near freezing, the sewage first rose and then sank as the temperature of the sewage-river mixture approached 39° F.

Introduction—Studies sponsored by the Atomic Energy Commission and conducted by the U. S. Geological Survey on the Mohawk River, at and downstream from the Knolls Atomic Power Laboratory (KAPL) near Schenectady, N. Y., provide data on river hydrology, quality of water, suspended sediment, and river-bottom materials. As part of these studies, three radiotracer experiments were performed in 1953–54 to determine the path and dilution of KAPL sewage under various river conditions. This paper, which is based on a report [*Simpson*, *Beetem*, and *Ruggles*, in preparation], describes the third and most extensive experiment, but draws on the data of the two preceding ones in presenting interpretive conclusions. The exploratory nature of the work made it necessary to begin in a small way and build each experiment on the results of the preceding ones.

Additional data were obtained through the participation of two independent groups: (1) a New York State Department of Health group collected and analyzed river-water samples from a series of stations between KAPL and Cohoes, some 14 miles downstream; (2) a Harvard University group collected samples and made measurements with an immersible GM-tube in various places near the KAPL sewer outfall. The *New York Department of Health* [1954ab] data was subjected to an interpretive study by *Parker* [1955] of the Harvard Group, but the Harvard data have not been published.

Location and hydrologic and physical conditions—KAPL is in east-central New York near the city of Schenectady, on the right (south) bank of the Mohawk River, about 15 miles upstream from its confluence with the Hudson River at Cohoes (Fig. 1). From Cohoes to KAPL and for many miles upstream, the Mohawk River is part of the Erie Canal system. As such it consists of a series of navigation pools, each impounded behind a permanent or a movable dam. In this study we are concerned mainly with two pools, one at KAPL impounded behind a dam at Vischer Ferry, herein called Vischer Ferry pool, and the pool immediately below it, herein called Crescent pool. Vischer Ferry pool extends from Vischer Ferry dam, which is about 1.7 miles downstream from KAPL, to a movable navigation dam at lock 8, which is about 9.0 mi upstream from KAPL, giving a total pool length of 10.7 mi. The average width of this pool is 940 ft. The minimum channel depth maintained for navigation is 14 ft, but near KAPL a maximum pool depth of 36 ft occurs; average depth at the KAPL section is about 20 ft, and width is about 700 ft. The quantity of water impounded between KAPL and Vischer Ferry dam when the pool is at flashboard crest is about 130,000,000 ft^3, about 10,000,000 ft^3 being impounded per foot of depth for the top three feet. Total pool impoundment is approximately five times greater than that contained in the section between the dam and KAPL.

Vischer Ferry dam is a permanent concrete dam serving both navigation and the production of hydrolectric power. It is 1920 ft long and 36 ft high, with a crest elevation of 211 ft above sea level. Flashboards 2¼ feet high are installed during about ten months of the year. The hydroelectric power station at the left (north) end has a capacity of about 3000 cfs, but operation is intermittent during summer and fall because river

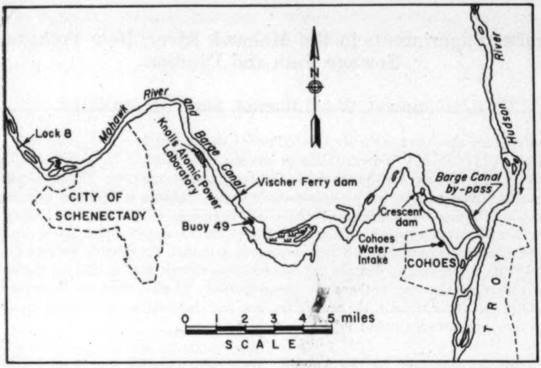

FIG. 1 – Lower reach of Mohawk River showing location of KAPL

discharge is less than station capacity. Lock 7 of the barge canal is at the right (south) end of the dam. Discharge resulting from lockage and leakage averages about 100 cfs. Spillage over the dam ordinarily occurs only during annual spring floods and takes place along the full length of the dam; at other times minor spillage can usually be discharged through waste gates near the hydroelectric power station. River sediment to a maximum thickness of 20 ft has accumulated in the pool on the upstream side of the dam.

Crescent pool extends from Vischer Ferry dam downstream about 9.6 mi to Crescent dam. This dam also is of concrete and also is operated in conjunction with a hydroelectric power station; operation of the two dams is roughly similar.

The discharge of the Mohawk River (drainage area 3456 sq mi) is gaged at Cohoes, about 14 miles downstream from KAPL. There is no important tributary between Cohoes and KAPL, and average daily discharge at the two places is virtually identical. Average discharge since 1918 is about 5700 cfs. Low-flow discharge during the summer and early fall is about 1000 cfs; during August 1954, when Test 3 was performed, discharge out of Vischer Ferry pool was roughly as follows: 2000 cfs between 6h 00m and 18h 00m, and about 100 cfs for the remaining 12 hours of each day.

Isotope discharge—Test 3, begun August 9, 1954, was designed to obtain hydrological data at a time when KAPL sewage was cooler and denser than river water. Sewage temperature was 68°F and river temperature was 76°F. On the basis of temperature alone, the sewage was about 0.10 pct denser than river water.

Beginning at 09h 08m (EST) and ending at 12h 20m, 31.60 liters of an aqueous solution of KH_2PO_4, containing 4.53 curies of phosphorus^{32}, was discharged at a constant rate into the Mohawk River through the KAPL sewer, or at an average discharge of 23.6 millicuries per minute (mc/min). The rate of sewage discharge was 200 gal/min (gpm), or 756 liters per minute. Hence, the average concentration of isotope leaving the sewer outfall was 31.2×10^{-6} millicuries per milliliter (mc/ml).

P^{32} was chosen as the radioisotope because (1) it is relatively harmless; (2) it emits short-range beta particles only, making it relatively simple to measure concentration with immersible GM tubes; (3) it has a convenient half-life of 14.3 days.

The isotope-sewage mixture flowed through 56 ft of 30-inch concrete pipe between the manhole where the isotope was introduced and the outfall on the river bottom. The outfall is about 15 ft offshore and under a depth of water that varies with river stage but averages about eight feet. About two-thirds of the 56-ft length is submerged below river level. Measurements made in Test 1 when sewage was warmer than river water showed that the isotope and sewage were not completely mixed at the outfall, and that the maximum isotope concentration of the sewage was twice the average. Although a similar measurement was not made in Test 3, it will be assumed that the same relationship prevailed, and that the maximum isotope concentration at the outfall was twice the average, or about 60×10^{-6} mc/ml. This is equivalent to about 140×10^{3} disintegrations per minute per milliliter (dpm/ml).

Measurement of isotope in river and interpretation of data—The path and concentration of the sewage-isotope mixture was measured in the river in two ways: (1) immersed GM-tubes with appropriate scalers powered by portable A C generators gave on-the-spot measurements at the river sections shown on Figure 2 and elsewhere as mentioned, and (2) collections of river-water samples for subsequent laboratory analyses. The data obtained with immersible GM-tubes will be considered first.

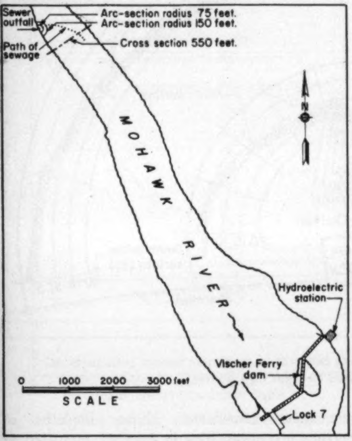

FIG. 2 – Mohawk River between KAPL and Vischer Ferry Dam showing location of sewer outfall, location of sections measured with immersible GM-tubes, and path of sewage, Test 3

Data from immersible GM-tubes—GM-tube measurements were made from three different boats: a catamaran as shown on Figure 3, a buoy tender borrowed for the occasion from the New York State Department of Public Works, and a rowboat. The catamaran and buoy tender carried all instruments aboard, but the rowboat carried only a GM-tube on a 200-ft lead, the remaining instruments being set up on the KAPL dock. The rowboat was attached to the dock by a rope line. During the three-hour period of isotope discharge, the rowboat measured concentration in two circular arc sections, one of a radius of 75 ft from the dock and the other of a radius of 150 ft. The sewer outfall was about 10 ft from the center of curvature.

Figure 4 shows isopleths of maximum isotope concentration in dpm/ml, plotted on polar coordinates, based on the maximum concentration measured at each point occupied by the GM tube. The GM-tube readings, in counts per minute (cpm), were converted to dpm/ml by the relation dpm/ml = 2 × cpm as obtained empirically for the tubes by laboratory test. As shown by the isopleths, sewage moved in a relatively narrow path down the slope of the river bottom, nearly

perpendicularly to the direction of river flow, for at least 150 ft. River discharge at the time was about 2000 cfs and average river velocity in this zone was on the order of 0.1 ft/sec. The change in concentration with distance from the outfall will be discussed later.

While the rowboat was making its measurements, the catamaran surveyed a river cross section 550 ft downstream from the outfall. The catamaran was attached to a tagline stretched across the river, and the tagline served both as anchor and as position marker. Figure 5, plotted on rectangular coordinates, shows isopleths of maximum concentration in dpm/ml, measured at this section. The main concentration of sewage here was flowing close to the deepest part of the river channel and its direction presumably was about parallel to that of river flow; however, the maximum concentration no longer was on the river bottom, but was about one-quarter of the way up.

Finally, the buoy tender roamed between the rowboat and the catamaran and in upstream waters, to try to define the path of sewage and in particular to watch for possible upstream movement. No tendency for sewage to move upstream during the period of isotope discharge was detected. (The deepest part of the river bottom opposite the KAPL outfall slopes upstream toward the bottom of a closed depression. It seems possible that during periods when the hydroelectric plant is shut down and river discharge is near zero, relatively dense sewage might move into the depression.) The path of sewage based on all GM-tube measurements made during the period of isotope discharge is shown on Figure 2.

Each of the three sections surveyed shows a small region where measured concentration of activity was a maximum. It is assumed that steady-state conditions prevailed at the time the maximum measurements were taken. In Figure 6, the log of the maximum measured concentration at each section is plotted against distance from outfall. The three points fall on a straight line. The log of the calculated maximum concentration at the outfall mouth also falls on the same straight line. This relationship indicates that in about the first 800 ft of sewage travel, the distance rate of change of maximum concentration of isotope, and presumably of sewage, at any section was directly proportional to the maximum concentration at that section. By analogy with radioactive decay, it is convenient to speak of a concentration 'half-distance' or the distance of travel over which maximum concentration is reduced by a factor of two. In the case of the present experiment the half-distance was about 110 ft. (Results of Test 2 indicate that when relatively warm sewage rises to the river surface, the half-distance, if it exists at all, is very short. In that test the density difference was quickly dissipated and for at least 500 ft of travel the maximum concentration of sewage apparently was inversely proportional to distance from outfall.)

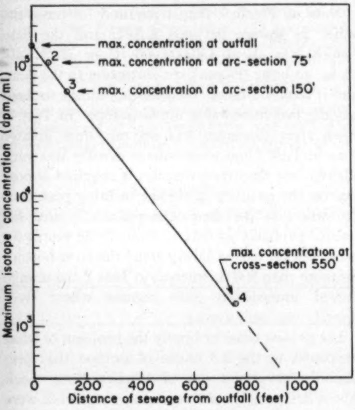

FIG. 6 – Relationship of isotope concentration to distance from outfall

By a simple calculation it becomes obvious that the half-distance relationship is not indefinitely valid. Extrapolating to 1600 ft on Figure 6, it is found that the calculated maximum concentration there would be less than that measured at Vischer Ferry dam, some 7400 ft farther downstream. Hence, it is concluded that, a short distance beyond the 800-ft point, the half-distance relationship is replaced by something else.

Water-sample data—Several hundred samples of

FIG. 7 – Relationship of isotope concentration to time and cumulated river discharge at Vischer Ferry Dam and at Buoy 49, Test 3; Vischer Ferry Dam is about 1.7 mi and Buoy 49 is about 2.8 mi below outfall

river water were taken and analyzed by the three participating groups. These data and their interpretation appear in the publications listed under REFERENCES. In order to round out this discussion of the movement of sewage in Vischer Ferry pool, we shall present part of the data obtained at Vischer Ferry dam. Figure 7 shows the concentration of isotope, corrected for radioactive decay, passing through the forebay of the power station, plotted against cumulative river discharge from the time isotope discharge began at KAPL. The isotope concentration (in millicuries per 1000 cfs hr, which equals millicuries per 3,600,000 ft^3) was calculated from hourly samples taken by the Department of Health. The area under the curve measures the quantity of isotope that flowed past the dam. Under the main hump this quantity is 3.0 curies or 66 pct of the total original dose. If the two small humps in the tail of the curve also be included, the quantity is 3.2 curies or 71 pct of the dose. For the sake of comparison the data collected at Buoy 49, about a mile below the dam, are similarly plotted on the same figure. The percentage of total dose passing this station was about 60 pct.

Maximum concentration at Vischer Ferry dam was 2.96 dpm/ml (equals 136 mc/1000 cfs hr as shown on Fig. 7), measured 36 hr after isotope discharge began. The calculated maximum at the sewer outfall was 140 × 10^3 dpm/ml, and the maximum concentration at section 550 was 1.5 × 10^3 dpm/ml (Fig. 5) measured 4½ hr after isotope discharge began. Extrapolating on Figure 6 to a distance of 800 ft from the sewer outfall we estimate that in this interval the isotope was diluted 140 fold. In the remainder of the distance to the dam, some 8200 feet, the isotope was diluted an additional 330 fold. Or, nearly one third of the dilution occurred in about one tenth the distance between outfall and dam. Actually, the relative dilution close to the outfall must be greater than these figures indicate. Close to the outfall the three-hour-long discharge of isotope can be considered as a continuous point source insofar as the immersible GM-tube measurements are concerned, but at the dam the three-hour discharge is more nearly an instantaneous point source insofar as the hourly samples are concerned. If we were to compute the dilution at the dam considering KAPL sewage as a continuous point source, then the maximum dilution available is simply the ratio of river discharge to sewage discharge, which was about 2000-fold at the time of the test. Hence, if the dilution of maximum concentration in a continuous point source was about 140 fold in 800 ft, then the remaining 8200 ft could provide only another 14 fold dilution. It appears probable that the initial density difference between river water and sewage resulted in faster dilution in terms of distance from outfall than would have occurred in the absence of a density difference.

Note on Figure 7 that it required 1.3 times the water in storage between KAPL and the dam (which was about 130,000,000 ft^3 or 36 × 10^3 cfs hr) to bring the peak concentration to the dam, and it took 4.3 times the water in storage to flush out the last measurable bit of isotope. In Test 2, when river discharge was several times greater than in Test 3 and when sewage density was very slightly less than river density, it required almost exactly the quantity in storage to bring peak concentration to the dam. The reason for the difference probably is that in Test 3 the relatively dense sewage moved slowly along the river bottom for more than 800 ft, whereas in Test 2 the sewage moved immediately into regions where river velocity was near average.

Let us now consider briefly the problem of what happened to the 1.3 curies of isotope that presumably never got out of Vischer Ferry pool. About 250 samples of river-bottom materials were taken from 46 different locations in the pool in the three-week period following the day of isotope discharge. About 50 samples were taken prior to isotope discharge. An analysis of the results discloses that not more than 0.2 curie can be accounted for by adsorption of isotope on the river bottom. Therefore, the remaining 1.1 curie either was taken up by aquatic life that did not float out of the pool, or it did leave the pool but was unmeasured because of faulty sampling procedure. However, (1) the next two downstream sampling stations showed a regular decrease in quantity of isotope passing (concentrations at stations still farther downstream were too low to permit this calculation), and (2) results of analyses made at KAPL and at the Department of Health, for places where sampling overlapped, were nearly the same, thus tending to rule out systematic laboratory errors; therefore, we conclude that aquatic life probably was responsible and that such things as eels and fish and water chestnut took up about a curie of P^{32} in a period of 2½ days.

In closing we wish to mention a series of measurements made with an underwater resistance thermometer in December 1953. These measurements serve to illustrate the importance of density differences in controlling the path of sewage. It was found that when river temperature was near freezing, sewage first rose to the river surface; then, as sewage mixed with river water and approached a temperature of 39°F, the mixture sank to the river bottom. The rising and sinking occurred within the first 50 ft of sewage travel.

Acknowledgments—The experiments described in this paper are part of a larger program sponsored by the U. S. Atomic Energy Commission. The cooperation and assistance provided by the Health Physics unit of KAPL, under L. J. Cherubin, Supervisor are gratefully acknowledged. The Health Physics unit prepared and discharged the isotope, supplied the necessary radiological instruments, performed hundreds of radioanalyses of samples of water and mud, and provided technical counsel in almost all aspects of the work.

Radioactive Tracers in Hydrologic Studies

FRANK L. PARKER

Abstract—The use of radioactive tracers to study phenomena in hydrology that have not previously been easily amenable to investigation is proceeding at a rapid pace. A group of experiments was carried out in lakes and reservoirs in Massachusetts to determine eddy diffusion coefficients. The average eddy diffusion coefficient divided by the radius of the eddy was found to be 0.09 ft/sec. A group of experiments to determine the average velocity of streams and the dilution in streams by use of radioactive tracers was then performed. The diffusion coefficients found in the test of the streams were compared with the theoretical diffusion coefficients of G. I. Taylor for straight pipes and found to be larger due to the increased dispersion caused by bends and obstructions in the stream. A mathematical formulation for general use in determining dilution and dispersion in rivers and streams by radioactive tracers was established. A correction is made for the absorption and decay of the isotope depending upon its chemical and nuclear properties. Work is under way at Harvard University to delineate further the absorption coefficients of important isotopes under various conditions leading to a better determination of the eddy diffusion coefficient.

Radioactive tracers are becoming an important tool for hydrologic studies because of the low cost, ease of detection, small gravimetric quantities required, and absence of density problems. The tracer to be of maximum usefulness must (1) have a half-life long enough to remain detectable for the length of the experiment, (2) have beta or gamma energies, or both, sufficiently energetic so as to be easily detectable by Geiger-Müller tubes or scintillation crystals, and (3) must function as an integral portion of the water and not be absorbed, adsorbed, or exchanged preferentially.

No one tracer will fulfill all these qualifications for all tests but for most tests it is possible to choose some tracer that will satisfactorily fulfill the above requirements. Isotopes of various half-lives and energies are available and so the one best fitting the conditions of the test can be chosen. Anions, amphoteric ions, and complexed ions are usually least sorbed or exchanged and so should be chosen if possible. For many tests iodine^{131} with a half-life of 8.05 days, or ruthenium^{106} with a half-life of one year, will be satisfactory. For other tests complexed scandium^{46}, half-life 85 days, or cobalt^{60}, half-life 5.26 years could be used. Shorter half-lives are preferable so that the tests may be repeated without any activity from earlier tests influencing the results. Only one per cent of the initial activity still remains after 6.5 half-lives and after ten half-lives 0.1 pct of the original activity is present.

There are, of course, certain disadvantages to the use of radioactive tracers. (1) They are hazardous and suitable precautions must be taken. (2) Expensive electronic equipment is necessary for detection. (3) A rigid time table must be followed particularly if isotopes with a short half-life are used.

However, the sensitivity of detection and the lack of density effects would seem to outweigh these disadvantages. Fluorescein, the most commonly used tracer in hydrology, can be detected in concentrations as low as 10^{-1} parts per billion. Radioactive iodine^{131}, in contrast, can be detected by scintillation counting in concentrations as low as 10^{-7} parts per billion.

Previous uses of radioactive tracers—The first inadvertent use or misuse of radioactive materials in hydrology came after the explosion of the first atomic bomb at Alamogordo, New Mexico, in July 1945. The amount of radioactive fallout from this explosion was sufficient to contaminate the Wabash and Iowa Rivers at distances from the bomb of more than 1000 miles and to cause the fogging of photographic film packed with strawboard processed with water from these two rivers [*Webb*, 1949, p. 375].

In August 1946 the explosion of the underwater bomb at Bikini enabled *Munk* and coworkers [1949] to measure eddy diffusion coefficients by the spread of activity in Bikini Lagoon.

Since then, the detention time in ponds has been measured with iodine^{131} [*Archibald*, 1950, p. 111], scandium^{46} has been used to determine the movement of sand grains in the bedload of the Thames River [*Putnam* and *Smith*, 1956], and radioactive silver has measured the movement of sand grains along the sea floor [*Gilbert* and others, 1955].

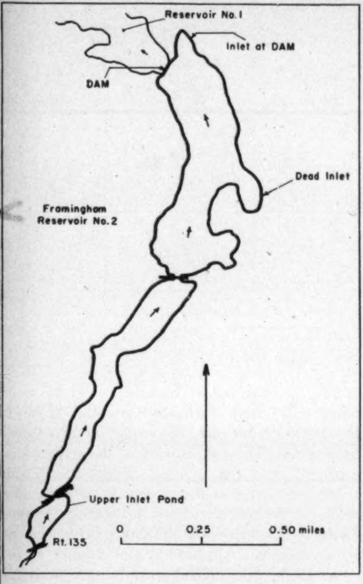

FIG. 1 – Map of the Framingham reservoirs of the Boston water supply system

Eddy diffusion coefficients have been measured by iodine^{131}, phosphorus^{32}, and rubidium^{86} [*Parker*, 1955] and dam sites have been investigated for possible piping by iodine^{131}, bromine^{82}, and chromium^{51} [*Hours*, 1955]. Sources of supply of water for wells have been determined by bromine^{82} and rubidium^{86} [*Hours*, 1955; *Fox*, 1952], and the rate of underground movement of waters measured by ruthenium^{106}, strontium^{89}, and cesium^{137} [*Kaufman* and *Orlob*, 1956; *Parker* and *Cowser*, 1957].

Eddy diffusion coefficients determined through use of radiotracers—Since 1951 a series of tests have been run at Harvard University to evaluate the dilution of radiocontaminants in surface waterways. To determine the dilution, it is necessary to measure the diffusion of the material. Since molecular diffusion is so much less than eddy diffusion the studies were restricted to eddy diffusion.

By eddy diffusion is meant the mass transfer of molecules in eddies of various sizes throughout the entire volume. The equation for the eddy diffusion coefficient is the standard Fick's equation.

$$\partial c/\partial t = \alpha^2 \partial^2 c/\partial x^2 \tag{1}$$

where c is the concentration
x is the distance from the dosing point
α^2 is the eddy diffusion coefficient.

For the two dimensional case (1) becomes

$$\partial c/\partial t = \alpha^2 \partial^2 c/\partial r^2 + (\alpha^2/r)\partial c/\partial r \tag{2}$$

where r is the radial distance from the dosing point.

The eddy diffusion coefficient was measured in a number of tests in the old Framingham Reservoirs of the Boston water supply system. These are out-of-service reservoirs on a standby basis and so the water is not used for drinking, bathing, or boating. The general area is shown in Figure 1.

The tests were performed by the instantaneous release of the activity into the reservoir from a bottle carried at fish pole length from a row boat. The dose varied from 2 to 20 millicuries of iodine^{131}. The water was then sampled as shown on Figure 2. By a solution of (2) the concentration is equal to

$$c = (M/4\pi\alpha^2 t)e^{-r^2/4\alpha^2 t} \tag{3}$$

where M is the amount of radioactive material initially added per foot of depth. Solving for the eddy diffusion coefficient, the average value of the eddy coefficient divided by the radius of the eddy was found to be 0.09 feet/second. This is the form of presenting eddy diffusion coefficients recommended by *Munk* and others [1949]. The execution of the test was much simpler than the previous techniques of dropping dye from planes and photographing their spread or of dropping mimeograph paper from airplanes and measuring its spread from photographs taken at intervals.

A series of tests was also run in an out-of-use pipeline connecting two of the Framingham reservoirs. A plot of one of the test results is shown in Figure 3. Analyses of the tests were made by a solution of the equation of pipeflow.

$$c = (w/2r^2\pi^{3/2}\sqrt{\alpha^2 t})e^{-(x-\mu t)^2/4\alpha^2 t} \tag{4}$$

where r is the radius of pipe
w is the mass of activity
μ is the mean velocity

The average eddy diffusion coefficient for the pipeline tests was 4 ft^2/sec. This value was determined by use of Thomas' [*Parker*, 1955, p. 4–20] non-parametric solution and Taylor's solution [*Taylor*, 1954, p. 446].

A final experiment was the determination of

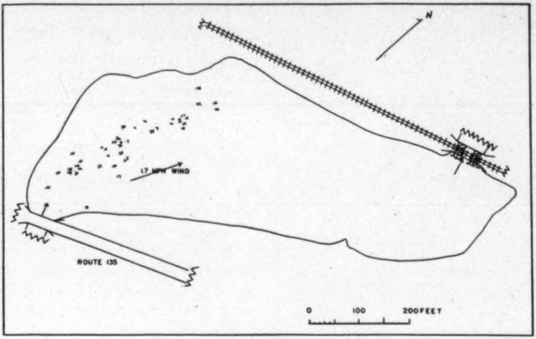

FIG. 2 – Sampling sites of reservoir test

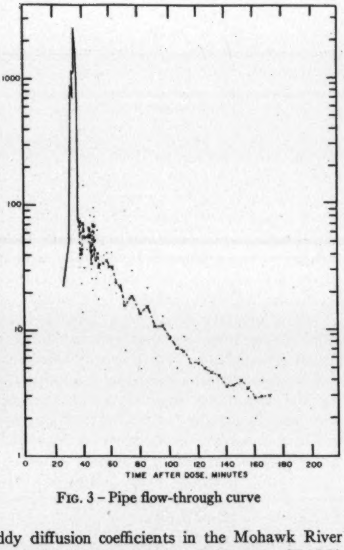

FIG. 3 – Pipe flow-through curve

eddy diffusion coefficients in the Mohawk River at the Knolls Atomic Power Laboratory (KAPL) (Fig. 4). The sampling stations of interest are KAPL, Vischer Ferry Dam, Buoy 49, Buoy 18B, and the Cohoes water plant. The first of three tests was primarily to check the instruments. During the second test, heavy concentrations of fallout material masked the tracer and this will continue to be a problem as long as bomb testing continues.

During the third test in August 1954, 4.5 curies of phosphorus^{32} were discharged into the Mohawk River through the plant sewer pipeline in a three-hour period. The temperature of the river water was 76°F and that of the effluent 68°F. The average discharge of the river was 1100 cfs. The results of the test are shown in Figure 5. As predicted by theory, as the activity proceeds downstream there is a reduction in peak heights, an increase in the longitudinal spread of the activity, and a reduction in the total amount of activity passing the sampling station. The reduction in activity due to flocculation and sedimentation, absorption, and biological uptake is here called the river absorption coefficient, N. It is postulated that this reduction may be fitted by an exponential decay law. Then by use of (4) and taking into account the nuclear decay and river absorption, we have

$$c = (w/2r^2\pi^{3/2}\sqrt{\alpha^2 t})e^{-(x-\mu t)^2/4\alpha^2 t}e^{-(N-\lambda)t} \qquad (5)$$

where λ is the nuclear decay coefficient

N is the river uptake coefficient.

Since (4) affects only the distribution of the activity flux curve and not the area under the curve the total amount of activity passing the downstream station corrected for nuclear decay and river absorption must equal the amount dosed.

By plotting the detention time for the perfect tracer, no decay or river absorption, against the proportion of the initial dose flowing past each station (Fig. 6), it was possible to get an average decay and river absorption coefficient, 0.0156 per hour. Since the nuclear decay coefficient is known for phosphorus^{32}, 0.0021 per hour, the

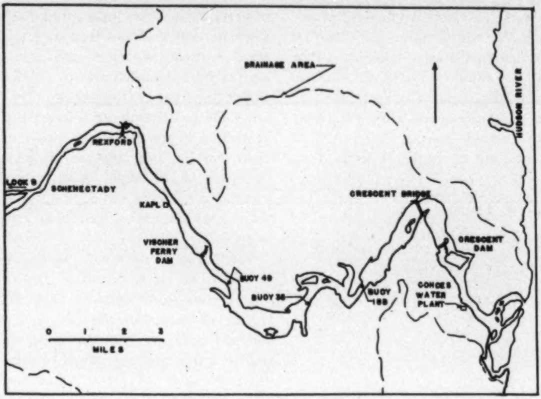

FIG. 4 – Map of the Mohawk River test area

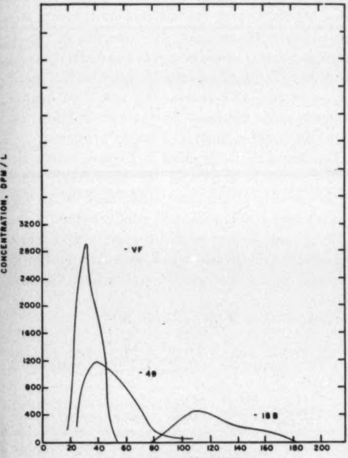

FIG. 5 – Mohawk River flow-through curves

coefficient for river absorption is calculated to be 0.0135 per hour.

The results of the test are shown in Table 1. The activity in samples from the Crescent Dam power house, located at the dam, and the Cohoes water plant were too close to background to be distinguished from background. Note that the eddy diffusion coefficients for the test are a good deal larger than the theoretical values. This is to be expected since the theoretical equation is based upon uniform and straight pipelines and the river is far from this. From an extension of the data from the flow-through curves the time to Cohoes water plant was computed to be 217 hours and the activity passing was 3.3 pct of the original dose. From an extension of the data of the eddy diffusion coefficients determined for the other reaches in the river, it was computed that the eddy diffusion coefficient for the river to mile 13, Cohoes water plant, was equal to 100 ft squared per second. If the conditions that prevailed during the test held throughout the year it was calculated that under steady state conditions 1600 curies of phosphorus^{32} could be injected into the river at KAPL each day and still have the concentration at the Cohoes water plant less than ten per cent of the maximum permissible concentration for phosphorus^{32} (2×10^{-5} microcuries per milliliter). By use of the maximum permissible concentrations for other isotopes and with other river absorption coefficients and nuclear decay coefficients, it would be possible to compute the maximum amount of other isotopes that could be discharged to the stream without downstream hazard.

Though it is true that most streams have demands for phosphorus and other radioactive materials, the extent of the demand is dependent upon a wide variety of physical, chemical, and biological conditions. Therefore, an analysis of this type must be used with caution until further experimentation has justified its reliability. It is conceivable that the amount of activity absorbed by the river could be released at a later date because of unusual water conditions. However, under the circumstances prevailing at the Knolls Atomic Power Laboratory and on the basis of the tests run and the analyses made, it has been possible to discharge low-level wastes safely into the Mohawk River without hazard to the downstream users and at substantial savings to the Knolls Atomic Power Laboratory. Downstream checks, of course, are made to determine whether there is any concentration of activity in the mud and biota. Further work is continuing at Harvard University under an AEC contract to evaluate the river absorption coefficients and eddy diffusion coefficients under a wide variety of conditions for a number of isotopes.

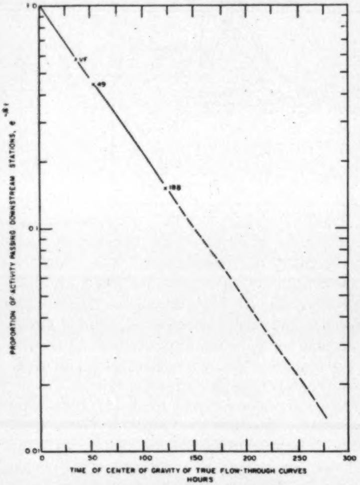

FIG. 6 – Plot of the relationship of detention time to the proportion of the initial dose passing to give combined decay and absorption coefficient

Future uses of isotopes in hydrology—Some other possible uses for tracers might be to investigate the relation of rivers with their tributaries by taking advantage of the fact that most of the radioactive fallout occurs as washout in the rain and so if the tributary should be rained upon and the main stem not, a free tracer would be available; the same test, of course, could be run with a prepared tracer limited only by the cost of the tracer. The investigation of the solitary wave could be facilitated by the use of tracers and particularly the amount of exchange of water between the wave and the rest of the water could be measured. The same measurements could be made for surges and this information would be helpful in determining dilutions downstream obtained by releasing large quantities of water upstream.

The Mohawk River data in Figure 5 were obtained from the report of the New York State Department of Health on the Mohawk River test which was a cooperative test administered by the U. S. Geological Survey with the New York State Department of Health, the Knolls Atomic Power Laboratory, and Harvard University participating.

TABLE 1 – *Per cent activity passing downstream stations Mohawk River, August 1954*

Station	River miles from KAPL outfall	Date and time of observed peak	Per cent passing	Per cent passing corrected		Time to center of gravity of flow-through curves		Eddy diffusion coefficients

The Travel Time of Radioactive Wastes in Natural Waters

G. T. BRYANT AND J. C. GEYER

Abstract—Radio isotopes discharged into natural waters (1) precipitate and settle, (2) adsorb on suspended and fixed surfaces, (3) enter the biologic cycle, or (4) in solution move with the flowing, mixing water itself. In the course of its life a single nuclide may shift with more or less freedom back and forth among these alternates. The paper deals with phenomena related to the fourth alternative. Natural waters and the substances carried in solution move and mix in response to complex forces of gravity, wind, tide, density, impact, shear, and inertia. Past studies of mixing and movement are drawn on to depict the time and space distribution of radioactive contaminates in natural waters. Tracer studies offer means for evaluating mixing and travel time which may in turn be used to forecast the fate of wastes continuously disposed of in water.

Water is nature's transportation agent. Through complex combinations of chemical, biological, and physical processes natural waters move everything they touch downward towards the oceans. The rate of attack and transport range from the rapid melting away of coast lines and river banks to the slow dissolution of granite mountains and their gradual transportation through alluvial valleys. Movement of the water itself and in particular the movement of flood waves, have received a great deal of study. In contrast, movement of the materials transported by water has received much less attention relative to its great significance.

Attention, therefore, is directed toward phenomena involved in the transportation of suspended and dissolved substances by the waters flowing down rivers and through tidal estuaries. Such materials may be conservative, that is, not change or disappear, or they may be non-conservative and change form or become inactive in the course of time. Sodium chloride is a conservative contaminant, biochemical oxygen demanding substances are non-conservative.

A radioactive substance is non-conservative only insofar as its activity is concerned. Sooner or later the atoms which produced the activity must find their way downstream. If a steady state were reached, just as many atoms would pass each section of the river as were discharged at the point of contamination. The average time of travel from section to section governs the amount of activity found at each point along a stream. This average travel time is almost always slower than the average rate of movement of the water.

The delay in time of transit relative to the water may be very long for atoms adsorbed on the channel surfaces or incorporated by sedimentation in the bottom sludges. It may be somewhat less but still quite long for atoms which enter the biological cycle. On the other hand, the radio-isotopes that escape detention by sedimentation and adsorption, move along downstream at rates that are at least in the same order of magnitude as the average rate of movement of the water. For this reason the flow time in water courses must be known to predict behavior of the contaminant.

Flow time in rivers by the use of tracers—Several earlier workers, [*Allen*, 1923, p. 285; *Barbagelita*, 1928, p. 789] used chemicals to determine flow times and quantities of flow in hydraulic structures. More recently, *Archibald* [1950], *Thomas* [1954], and *Parker* [1955], have used radio-isotopes as tracers to determine flow times in hydraulic structures and in natural waters. Regardless of the type of tracer used the problem is to predict the behavior of the water or of pollutants introduced to the water in the light of the field data collected from the tracer study.

Taylor [1954] has presented a theoretical analysis for the dispersion of matter in turbulent flow based on the classical diffusion equation with the conditions that the channel be of uniform cross-section, constant net velocity, and constant eddy diffusivity. He arrives at a solution of

$$C = M/2A\ \sqrt{\pi K t}\ \exp\left[-(x - vt)^2/4Kt\right]$$

where

C	concentration of tracer
A	cross sectional area of channel
t	time after introduction of tracer or pollutant
x	distance from point of origin
$\bar{v}$	mean velocity of the stream
K	overall coefficient of diffusivity
M	initial mass of tracer

This equation describes the dispersion of diffusible matter about a point which moves with the mean speed of fluid flow. The distribution is symmetrical and Gaussian with respect to x at fixed values of t.

Pritchard [1954] and *Kent* [1955] have derived equations for the behavior of diffusible pollutants in estuaries yielding the general equation

$$\frac{\partial \bar{q}}{\partial t} = -V\frac{\partial \bar{q}}{\partial x} + \frac{1}{A}\frac{\partial}{\partial x}\left(AK_q\frac{\partial \bar{q}}{\partial x}\right)$$

where

$\bar{q}$ mean concentration of pollutant
K_q horizontal eddy diffusivity
S initial mass of pollutant

Only when the estuary is of uniform cross section, constant net velocity and constant eddy diffusivity is there an exact known solution.

Their solution under these conditions

$$q = S/2A\sqrt{\pi K_q t}\exp\left[-(x - \bar{V}t)^2/4K_q t\right]$$

gives the same equation as that derived by Taylor.

The experimental results of Taylor, Kent, and Pritchard show that the tracer behaves as predicted by the equation. The center of mass of the tracer moves with the speed equal to the mean velocity of the water and the tracer is dispersed both upstream and downstream from the center of mass such that the concentration-space distribution of the tracer is symmetrical and Gaussian. This means then that the movement of the center of mass of the tracer is a measure of the mean velocity of the stream.

Unfortunately space-concentration curves cannot be readily determined in large scale field studies as this would involve a large number of sampling stations and simultaneous sampling at each station at frequent time intervals. The procedure in the field has been to determine the time-concentration distribution as this requires only two or three sampling points, and to use some parameter of this distribution (mode, median, mean, range) as a measure of the mean velocity of the stream.

Pritchard [1954] has observed that the modal and mean values of time-concentration curves occur at much earlier times than given by the modal value of space-concentration curves. This becomes apparent when looking at a series of space-concentration curves in relation to a fixed point. A curve which has its maximum at an earlier station may have a concentration greater at the point in question than when the space-concentration curve shows a maximum at the point in question. This would be particularly true for the condition of very large values of the eddy diffusivity coefficient as the space-concentration curves would then flatten very rapidly as they were displaced downstream. Thomas has indicated that the centroid of the time-concentration curves obtained in his studues gave good agreement with the mean flow time or 'theoretical' detention period, that is, channel volume divided by discharge, for the reaches measured.

When one or more of the parameters (velocity, cross-sectional area, or eddy diffusivity) are functions of x, then the space-concentration curve is no longer Gaussian and symmetrical. Consider the case in which the eddy diffusivity is a linear function of x with increasing values of K_q in a downstream direction. The lower leg of the space-concentration curve will be subjected to a greater diffusion influence than the upper leg and as a result the curve will become skewed. The value of the center of mass of the curve will shift from that of the peak value. This will also affect the shape of the time-concentration distribution curve and the centroids of such distribution will fall further from the centers of mass of the space-concentration distribution than in the previous case.

It is interesting to observe Pritchard's equation under the conditions of linear variation of K_q with x. With uniform cross-section the equation may be written

$$\frac{\partial q}{\partial t} = \left(\bar{V} - \frac{\partial K_q}{\partial x}\right)\frac{\partial q}{\partial x} + K_q\frac{\partial^2 q}{\partial x^2}$$

The first term now becomes the mean velocity of the center of mass of the diffusant and includes

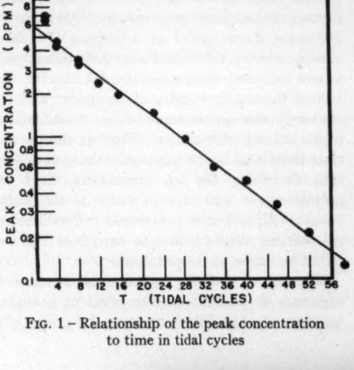

FIG. 1 – Relationship of the peak concentration to time in tidal cycles

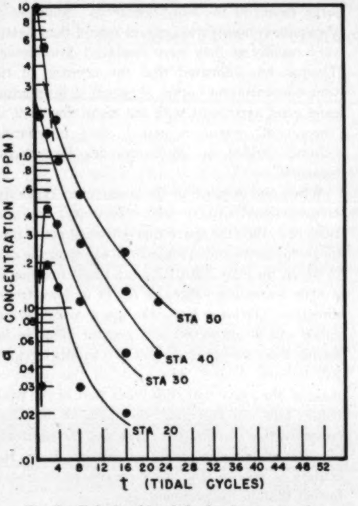

FIG. 2 – Relationship of the local concentration to time in tidal cycles for stations above the release point

a term in K_q as well as the mean velocity of the stream. Under the condition that K_q increases with x it becomes evident that increasing values of K_q in a downstream direction reduces the effect of the mean river velocity in transporting materials downstream. That is the pollutant moves with a mean velocity somewhat less than that of the water.

Such behavior is actually shown to occur in the estuary studies, made by *Pritchard* [1954] using the Delaware River model at Vicksburg. In these studies, which are described more fully below, peak values of the space-concentration curves lag behind the center of mass of the tracer and the center of mass of tracer lags behind the calculated mean velocity of the water. Since at the present time there is no known solution to the above equation describing the lag phenomena, field experiments are necessary in order to determine values of K_q and other parameters and mechanical calculations must be used to determine the distribution curves of the pollutant.

The existence of this lag phenomena makes it necessary to account for the effect of changing intensity of eddy-diffusivity along the course of a river when planning or interpreting field tests made to determine flow times.

Travel time in estuaries—In contrast with flowing streams, where the predominant motion is the down river flow in response to gravity, the waters of tidal estuaries are caused to circulate by forces of tide, wind, and density gradients as well as by the river inflow. Materials which find their way into tidal estuaries circulate with the water and are gradually diminished in concentration and flushed away. The time for a contaminant to be moved out of an estuary or at least out of one section of it, is ordinarily referred to as flushing time rather than travel time.

Estuarial circulation and flushing have been studied intensively by oceanographers for a period of about ten years. In the late 1940's *Ketchum* [1949, p. 64, 1950, 1951ab, 1955] attacked this problem and has since published numerous articles dealing with travel time and the dispersion of pollutants in estuaries. Ketchum's work is based on the hypothesis that the effective mixing length in an estuary is equal to the mean distance traveled by a water particle on the flood tide. Determination of this distance involves dividing the estuary into segments so related that the volume of each

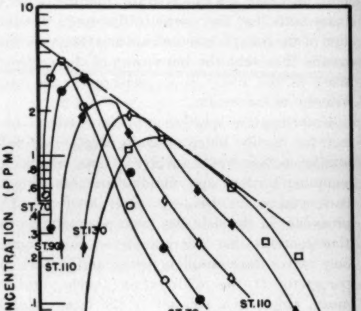

FIG. 3 – Relationship of the local concentration to time in tidal cycles for stations below release point

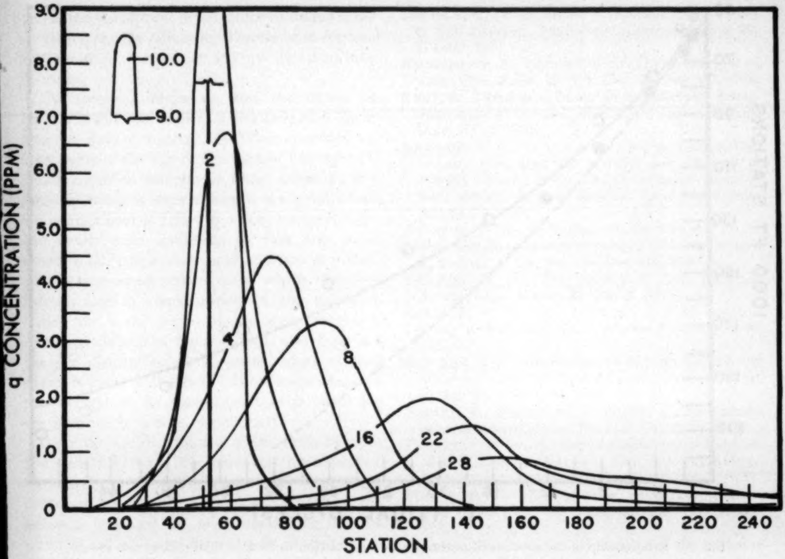

FIG. 4 – Longitudinal distribution of contaminant after designated number of tidal cycles

segment at low tide is equal to the volume of the next upstream segment at high tide. Although the method is empirical it has been found to produce results that are in good agreement with observed salinity gradients in portions of a variety of estuaries.

Stommel and *Farmer* [1952], *Arons* and *Stommel* [1951], and *Stommel* [1953] used a somewhat more sophisticated mathematical approach based on differential equations for continuity and for salt-transfer or diffusivity. The resulting differential equation is the same as that used by Pritchard. It was found that data from actual salinity surveys plotted well upon one or another of the family of curves predicted by the theory. However, the method provided no *a priori* method of predicting what the situation might be in absence of actual measurement.

Pritchard [1954] as mentioned above, investigated the travel time or flushing rate in a model of the Delaware River constructed by the Corps of Engineers at the Vicksburg laboratory. This model, which covered the reach from Trenton to the Capes, had scale ratios of 1 to 1000 horizontal and 1 to 100 vertical. Vertical metal strips imbedded in the concrete provided the degree of turbulence necessary to produce at all river flows in the model, the salinity gradients observed in the prototype.

The tests reported by Pritchard were made by injecting slugs of dye at various points in the estuary and observing the concentration of the dye at a large number of stations over many tidal cycles.

The peak concentration declined very rapidly during the first two tidal cycles and then fell away along a semi-logarithmic die-away curve (Fig. 1). The variations in concentrations with time at fixed points upstream and downstream from the point of contamination appear in Figures 2 and 3. The dye was introduced and all measurements of concentration were made at high water slack. Figures 2 and 3 do not show directly the distribution of the dye at any tidal cycle, but merely record the amount of dye at a given station on a given cycle. For example, the peak concentration at Station 150 occurred on the 22nd cycle and was 1.3 ppm. At this time the point of highest concen-

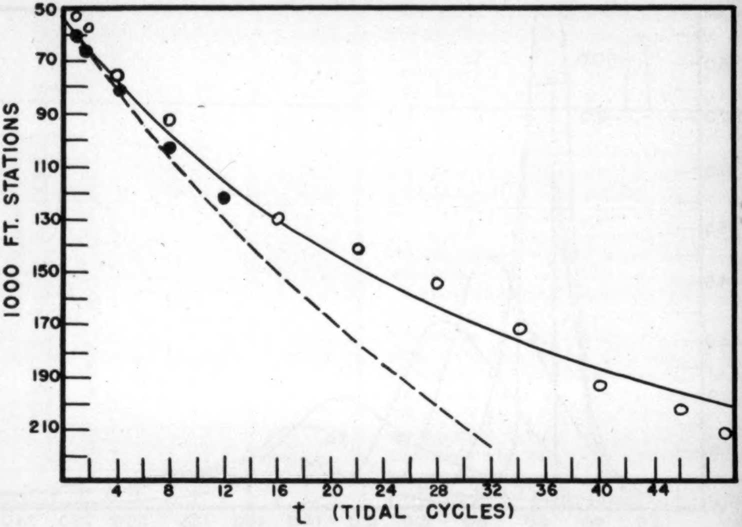

FIG. 5 – Relationship of the movement of the peak concentration to time in tidal cycles; also shown (broken curve) is the calculated net downstream water movement based on river inflow

tration in the estuary was 1.9 ppm at Station 140. On the 28th cycle the concentration of 0.9 ppm at Station 150 represents the true peak of the distribution curve for the dye. A better picture of the situation with regard to location of the dye may be obtained from Figure 4 which shows the concentration throughout the estuary at fixed times. The remarkable Gaussian normality of the distribution is evident in Figure 4. The very rapid initial decline in peak concentration during the first two tidal cycles is probably due to improper scale ratio for the local turbulence. Intense local turbulence occurred in the model around and in the lee of the vertical plates installed to produce in the model the general pattern of tidal action and salinity gradient observed in the prototype.

Figure 5 shows the downstream movement of the peak of the distribution curve. This peak lags appreciably behind the net average downstream movement of the inflowing river water. The reason why the dissolved material moves downstream more slowly than the water is explained by the equations already presented.

Since the differential equation cannot be solved mathematically, recourse must be had to experimentation in order to evaluate the parameters and apply the theory. This has been done by *Kent* [1955] in a dissertation which will soon be published.

Field measurements using slugs of tracers to determine the travel time and mixing in an estuary involve many severe difficulties in addition to great labor. It appears, therefore, that construction of a model provides the only reasonable approach to solution of such problems insofar as estuaries are concerned. Models are of course expensive. Once built, however, they are useful for many studies of economic importance other than the determination of flushing times. Enough work has already been conducted with models to indicate their reliability. Their successful use depends on the availability of the information necessary to confirm their behavior. In brackish-water estuaries, field measurements of salt concentration gradients over long periods involving different sequences of river flows provides the necessary data. In fresh-water estuaries as in rivers there is no alternative to tracer studies. These must be conducted in sufficient detail either to evaluate the coefficient of eddy diffusivity directly or to confirm a model in which more detailed investigations may be made.

The foregoing discussion and the curves of Figures 1 to 5 for studies on the Delaware River apply to slugs of contaminant. What is needed are predictions of the age distribution of the material which occurs in samples of water taken at any place upstream or downstream from a point where the contaminant is added as a continuous stream. For steady state conditions of river flow, tidal range, wind, temperature, and addition of pollutant, a time-concentration curve which describes the increase in concentration of the pollutant during the initial period of rise after starting a constant addition of the pollutant, also describes the age distribution in a sample taken at that point. A curve of this type has the same shape as the integral of the time-concentration curve for the addition of a slug of pollutant.

Once the age distribution of the radio-isotopes in a sample is known it becomes possible to predict the amount which should be found or through difference between the amount predicted and the amount measured to learn something of the physical and biological detention along the path of flow. This would be exceedingly valuable information in connection with pollution and self purification studies. It is unlikely, however, that detention can ever be estimated with sufficient accuracy that measurement of the downstream residue from a continuous discharge could be used to calculate time of flow of radioactive wastes in rivers and estuaries. Tracer tests supplemented by model studies remain the only tools for determining travel time of radioactive wastes in natural waters.

Tracing Moisture Movement in Slick-Spot Soils with Radiosulfur: Part I*

J. V. JORDAN, G. C. LEWIS, AND M. A. FOSBERG

Abstract—Preliminary greenhouse tests using slick-spot soil and associated soil in columns indicated that cobalt^{60} and sulfur^{35} moved through the soil columns and appeared in the first drainage water. The first field experiments were run south of Boise on the Sebree-Chilcott associated series. Radiosulfur was used in the form of dilute sulfuric acid soaked into absorbent cotton. Each wad was specifically placed in or adjacent to a slick spot. After several months, soil samples from these tagged slick spots indicated that some characteristic water movement had occurred. Improved techniques have been developed and the study will expand to include slick-spot soils in irrigated and dryland areas.

Introduction—In the irrigated areas of southern Idaho there are estimated to be 300,000 acres of slick-spot soils. These are solonetz-type soils in the Sierozem great soil group and are represented here by the Sebree and the associated Chilcott series. The Sebree series of slick-spot soil is characterized by poor structure and poor water penetration caused by a deflocculated condition caused by a high sodium content. These slick spots vary in size from two feet to more than 50 in diameter and may represent from 10 to 50 pct of the landscape. During the past 25 years these soils have resisted all known methods for soil improvement. About three years ago the Idaho Agricultural Experiment Station launched a systematic study of the morphological, chemical and physical characteristics of slick-spot soils.

Preliminary studies have indicated that soil-moisture movement in and around slick spots may be one of the factors contributing to the formation of, and apparent permanence, of slick spots in soils. Nothing was known concerning the nature or extent of this moisture movement. In order to obtain such information, radioactive tracers were used to study the moisture movement. Methodology in this procedure is the principal objective of this report.

Literature review—There are relatively few references in the literature concerning the use of tracers for determining surface or subsurface movement of water. ***Putnam*** and others [1954] used the tracer, scandium^{46}, to determine underwater movement of sand and silt. These experiments are concerned with river siltation and the offshore movement of sand on the sea-bed. ***Jefferson*** and others [1953] employed sodium^{24} for finding leaks in sections of buried water mains up to five km in length. ***Rogers*** and ***Schilberg*** [1951] determined the initiation of convective flow through porous media by detecting counting rate changes in water dispersed throughout a bed of granular solids. Phosphorus^{32} was the tracer used. ***Kimura*** and ***Ikeda*** [1951] used radium^{224} to measure the flowing velocity of water through pipe. ***Inose*** and others [1955] have studied techniques for determining littoral drift.

Materials and methods—The first problem was to find a suitable tracer, preferably one which would fit into the existing analytical program. Sulfur^{35}, a soft beta emitter with a half-life of 87.1 days, was the first selection, since sulfate was one of the anions being determined in the chemical study. Cobalt^{60}, a gamma emitter with a half-life of 5.3 years, was the second choice. These isotopes were first used in a greenhouse experiment. Soil columns were set up in steel cylinders, 18 inches tall by nine inches diameter. Each cylinder was filled with the soil representing a particular horizon of the Sebree slick-spot soil and the Chilcott associated soil. These were prepared in duplicate, one set receiving sulfur^{35} and the other set cobalt^{60}. A depression about $\frac{1}{2}$ inch deep was made in the center at the soil surface of each cylinder and into the depression was poured one milliliter of solution carrying either sulfur^{35} as H_2SO_4 or cobalt^{60} as $CoCl_2$. The amount of activity in each case was about one millicurie. The soil cylinders rested on drainage plates so that drainage could be collected. Measured amounts of water were added to the soil cylinders every day so that the surface never dried out. All drainage was tested each week for radioactivity. However, in each case it was important to catch the first drainage from each cylinder to determine whether the tracer was in the soil moisture

[b] Experiment suspended.

front. An aliquot of the drainage was evaporated to dryness, weighed and the specific activity determined. Data for this preliminary experiment are presented in Tables 1 and 2.

Data in Table 2 show that both radiosulfur and radiocobalt moved through the soils continuously with the moisture. The experiment using cobalt^{60} was soon discontinued in favor of sulfur^{35}. Sulfur^{35} was a more convenient isotope to transport and to work with in the field and laboratory.

On the basis of this information, field work on slick spots in the dry range land near Boise, Idaho, was started. In September 1955 slick spots were selected. One millicurie of sulfur^{35} in H_2SO_4 was placed in a specific position in or outside each slick spot as shown in Figures 1–7. Procedure for this application began in the laboratory and consisted of pipetting a one milliliter aliquot of the tracer solution into a small glass vial. This volume of solution contained one millicurie of sulfur^{35}

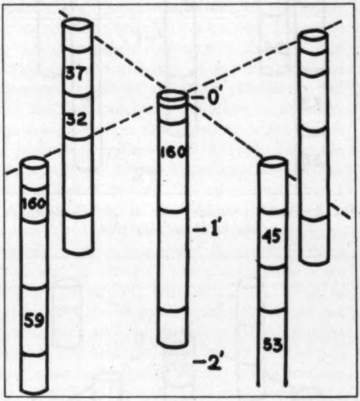

FIG. 1 – Spot A; outside spot on surface, May 1956

activity. A piece of absorbent cotton was pushed into the vial so that the cotton soaked up the active solution. A number of vials were prepared for field use. A soil auger was used to make entrance into the test sites for placement of the tracer. The absorbent cotton was removed from the vial by tweezers and dropped into the boring made by the auger. The soil borings were filled in with soil in the order in which it had been removed.

In May 1956 the slick-spot sites were sampled. From September 1, 1955 to May 31, 1956 the average precipitation was 11.47 inches according to U. S. Weather Bureau records taken three miles to the north. Certain sites were sampled again in August. From May 1 to August 31, 1956 the average precipitation was only 1.94 inches.

The tagged slick spots were sampled using a Kelley core sampler taking four-inch undisturbed soil core. In May, each tagged spot was generally sampled in five positions. These were as follows: Down through the profile along the vertical axis of original placement of the tracer; then cores re-

moved one foot to the north, south, east and west of this central axis. Soil samples were taken from the various horizons. Precautions were taken to avoid cross-contamination of samples by stripping off the outer inch of soil from the soil cores. The samples were air-dried and kept for physical and chemical analyses. In August some spots were sampled at a two-foot radius from the central axis. Radiosulfur determinations were run on an aliquot from the ammonium acetate extraction procedure [*Hosking*, 1948]. Barium sulfate was precipitated in the aliquots, filtered by suction on stainless steel filters through a one-inch diameter No. 42 Whatman filter paper. The filter disc was dried and the activity measured in an RCL preflush flow counter using Q-gas. On the basis of the soil sample and aliquot taken, a specific activity was calculated as counts per minute per gram of soil. These values were posted on the diagrams illustrated in Figures 1 to 7. Natural radioactivity existing in these soils and present in the ammonium acetate extract was determined and this background activity was found to average 30 counts per minute per gram of soil. Various workers have reported on the existence of natural radioactivity in soils. *Gibbs* and *McCallum* [1955] indicated that soil radioactivity depends partly on the rock materials from which the profiles were developed. Consequently, values of 30 and less are disregarded in these data. However, this does not imply that the added tracer did not move into those soil zones but suggests that the methods of measuring the sulfur^{35} activity were not sufficiently precise.

Vegetation samples, principally from sagebrush growing outside the perimeter of slick spots, were collected. Many samples contained considerable radiosulfur but so far it has not been determined whether the tracer had been absorbed by the roots penetrating into the slick spot or absorbed after the tracer had moved out.

Results and discussion—Results of the tracer movement shown in Table 2 are directly related to the soil descriptions presented in Table 1. Soil texture and the stability of soil structure are important factors in soil water movement. Not until the sixth week after moisture applications began did the water finally penetrate the Sebree B_2 horizon in cylinders 20 and 26. However, radioactivity was present in the first drainage from these cylinders and all the others in Table 2.

An examination of the soil core diagrams in Figures 1 to 7 reveals that the tracer did move from the point of placement in certain patterns which may be assumed to be characteristic of the moisture movement. Obviously, there was no correlation between moisture content of the soil core samples and the specific activities of these samples. The determinations were run at the time of sampling so the specific activity values posted in the soil cores indicate the path of moisture movement from the tracer placement only.

In Figure 1, slick-spot A, the activity was placed just outside the spot, at a depth of about three inches. The May samplings indicate that moisture had moved downward and away from the slick spot. In Figure 2, spot B, the tracer had been placed outside the slick spot at a depth of 12 inches; that is, below the B_2 horizon but on top of the lime hardpan. Here the data show that the moisture moved upward to the surface and toward the slick spot but, as in Figure 1, the downward movement was away from the slick spot. In Figure 3, spot C, the tracer was placed outside the slick spot, 18 inches deep on the lime hardpan. In this instance, the greatest movement tended to be away from the spot. However, there was lesser movement upward toward the spot.

In Figure 4, spot 1, the tracer was placed in a slick spot but near the perimeter and on the surface. The only apparent movement here was slightly downward. However, a sagebrush sample collected outside the spot contained radiosulfur indicating there had been surface erosion and some surface runoff from inside the spot to the outside.

Figure 5, spot 2, illustrates the movement when the tracer was placed inside the spot but near the perimeter, 11 inches deep, below the B_2 horizon. The principal movement was upward further into the spot. There was lesser movement toward the outer edge. This spot was sampled in August. Figure 6, spot 3, was sampled in May and August. The August samples were taken on a 24-inch perimeter. Here the tracer had been placed inside the slick spot, 29 inches deep on top of the lime hardpan. The May samples indicated that the movement was upward and outward in all directions from the point of placement. The August samples showed that no movement took place at least as far as the 24-inch perimeter during the summer months, during which the average precipitation was only 1.94 inches.

In Figure 7, spot 4, the tracer had been placed on the surface and the spot sampled in August on a 12-inch perimeter. Results showed that the main movement was downward.

Conclusions—Results of this experiment indicated that radiosulfur is a suitable tracer for studying moisture movement in slick-spot and associated soil. This information may then lead to the understanding of slick-spot formation, and ultimately control and eradication practices.

Under the conditions of the experiment where precipitation was only about 11.5 inches, the tracer moved from the point of placement in definite directions, depending on the placement. Preliminary experiments had shown it reasonable to assume that the tracer moved with the soil moisture.

Where the tracer was placed outside the slick spot, at depths below the surface, the moisture moved both downward away from, and upwards toward, the slick spot. Where the tracer was placed inside the slick spot at depths below the surface, the moisture movement was upward. Of all placements, surface placement inside a slick spot showed the least moisture movement. Generally, the deeper the placement, the greater the moisture movement, suggesting that moisture already present at shallow depths was involved.

The Distribution of Radioactivity from Rain

LLOYD R. SETTER AND CONRAD P. STRAUB

Abstract—Under conditions similar to Cincinnati, Ohio, fallout is the result of rainout and snowout. Without precipitation there is little fallout even though the particulate activity of surface air is abnormally high. Much of the suspended activity in cistern water from rain will be removed by sedimentation. Over 90 pct of both the suspended and dissolved fallout becomes associated with soil and vegetation rather than appearing in surface waters. From the spring of 1953 to January 1957, the fallout of strontium^{90} (Y^{90}) in Cincinnati, Ohio, is estimated to be at least ten and probably not more than 30 millimicrocuries per square meter of surface area.

Fallout measurements, largely as precipitation, have been made on a continuous basis at Cincinnati, Ohio, since March 1953. The studies of 1953 [*Nader* and others, 1954] and 1954 [*Setter* and *Goldin*, 1956] were implemented in October 1953 by weekly or daily tests of the atmospheric particulate activity and by the operation of an experimental cistern near the site of the rain collector. Correlation is now possible between air-particle concentration and rainout (washout by precipitation) and distribution of activity between the separated solids and the supernatant liquid in the cistern liquid can be determined. This report includes data relating to activity levels in air particulates, rainfall, and certain Ohio rivers.

Methods—The methods of sample collection have been described [*Setter* and *Goldin*, 1956]. The precipitation values reported in Figures 1 and 2 are the means of values reported for six stations and were obtained from U. S. Weather Bureau climatological data. To compensate for differences in hours of collection some adjustment in these values was made.

Rainfall was collected in a pail-type sampler. Aliquot samples were filtered through membrane filters and the filtrates evaporated. The gross beta-gamma activity of the filter and dissolved solids was measured, and the results reported on an area basis. Repeat measurements on many samples were made to establish the decay rates of suspended and dissolved activities. When combined the suspended and dissolved activity usually exhibited an exponential negative decay rate of from 1.0 to 1.2 for known dates of bomb tests. For tests of unknown origin appropriate dates were selected to conform in general to this rate of decay.

The air-particulate activity of samples from January 1, 1955, to August 1956 was determined from swatch sub-samples representing roughly 80 m^3 of air filtered through glass fiber filters over a 24-hour period from the Lincoln Park area, Cincinnati [*Tabor*, 1956]. Continuous air sampling was initiated August 1, 1956. Air activity was obtained daily (except week-ends) by filtering 20 to 30 m^3 of air through a membrane (cellulose acetate) filter. Week-end samples were collected after one to three days. The membrane filter sample was placed in an aluminum dish, saturated with 95 pct alcohol, ignited, flash flamed with a Meeker burner, and counted for two 8-min. periods in an internal proportional counter. The beta counting was usually postponed for two days after collection to prevent the interference of short-lived naturally-occurring alpha and beta activity [*Setter* and others, 1957].

Precipitation, air particulate, and fallout activity—The results of precipitation in inches, air particulate activity in micromicrocuries per cubic meter ($\mu\mu c/m^3$), and the fallout activity in millimicrocuries per square meter ($m\mu c/m^2$) have been summarized in Figures 1 (1955 data) and 2 (1956 data). From the decay-of-rain samples the age of the activity was estimated and is shown for most of the samples in the legends of Figures 1 and 2. The rate of decay is plotted as broken lines.

Considering the particulate activity in air from stations in the Midwest (Cincinnati, Louisville, St. Louis, Chicago, Minneapolis, and Detroit) the average background level of approximately 0.05 $\mu\mu c/m^3$ in the fall of 1953 has increased to an arithmetic average level of 0.6 $\mu\mu c/m^3$ in 1954, 1.55 $\mu\mu c/m^3$ in 1955, and 2.26 $\mu\mu c/m^3$ in 1956. During continental tests in 1955, the activity in Cincinnati air (Figure 1) fluctuated from a high of 10 $\mu\mu c/m^3$ of rapidly decaying radioactivity to a low of 0.88 $\mu\mu c/m^3$. Due primarily to the more distant bomb-test areas and the consequent dispersion of activity and decay of short-lived iso-

topes there was less fluctuation in radioactivity levels (8.9 to 0.58 μμc/m³) during the Pacific and foreign tests of 1956. However, a higher sustaining level of air radioactivity was noted for the entire year.

Fallout from 15 rain collections made between March 15 and June 25, 1955 showed activity levels above 30 mμc/m², with the level in seven of these varying from 141 to 1370 mμc/m² (Fig. 1). Most of this activity was short-lived as shown in the decay curves. Relatively little radioactivity was observed in samples collected during the first two and last six months of 1955, but the activity collected was of longer half-life. Although the air was relatively active in December, precipitation and consequently the fallout was insignificant.

In 1956 (Fig. 2) the radioactive fallout in excess of 10 $m\mu c/m^2$ was common throughout the year. During this time air activity was moderately low (less than 3 $\mu\mu c/m^3$) except in September and October. The decay curves show that most of the fallout activity in 1956 was longer-lived than that collected in 1955.

A somewhat better appraisal of the amount of long-lived radioactive fallout may be obtained by considering the cumulative residual deposition. At Cincinnati, and presumably at all non-arid areas several hundred miles removed from the weapons test site [*List*, 1956], increased radioactive fallout appears to be associated with periods of rainfall and snowfall.

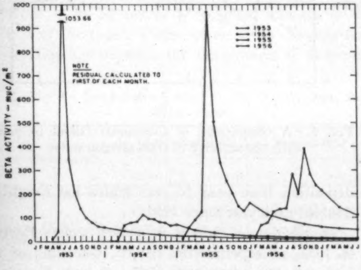

FIG. 3 – Residual fallout

The radioactive fallout, identified quite precisely as to age and rate of decay for the more radioactive samples and less accurately for the low-level radioactive samples, has been extrapolated to the first of each succeeding month. The cumulative residual activity in $m\mu c/m^2$ of Earth's surface, assuming no loss, is plotted as shown in Figure 3 for each of the four years of record from April 1953 to July 1, 1957. In each year there is a peak of activity during or immediately following test operations. High peaks of 1054 $m\mu c/m^2$ on June 1, 1953 and 970 $m\mu c/m^2$ on June 1, 1955 are shown for the two years of continental tests (1953 and 1955), whereas longer-lived peaks of 110 and 390 $m\mu c/m^2$ were observed on July 1, 1954 and October 1, 1956, respectively. Fallout during the latter periods was from Pacific and foreign test operations. The yearly deposition of observed fallout was extrapolated to one-year-old fission products.

One-year-old mixed fission products contain 3.9 pct strontium^{90} (yttrium^{90}) according to *Hunter* and *Ballou* [1951]. This value was used to cal-

[b] Weighed average.

culate the combined activity of $Sr^{90} - Y^{90}$ deposited for each of the four years as follows:

Year of deposition	One-year-old activity	Sr^{90}-Y^{90}
	mμc/m²	mμc/m²
1953	31.3	1.22
1954	37.5	1.46
1955	63.2	2.46
1956	150.4	5.87
Total 1953–56	282.5	11.0

Precipitation for each of the four years amounted to 22.9, 36.3, 44.7, and 41.8 inches, respectively, a total of 145.7 inches. On this basis the average activity of precipitation over the four-year period was 76.4 micromicrocuries per liter (μμc/l) of one-year-old fission product and 3.0 μμc/l of Sr^{90} (Y^{90}).

These levels in water appear insignificant, compared to the maximum permissible level of $Sr^{90} - Y^{90}$ in drinking water of 800 μμc/l [*U. S. National Bureau of Standards*, 1953]. However, it may be significant to observe the increase in the deposition from year to year which has roughly doubled each year since 1954.

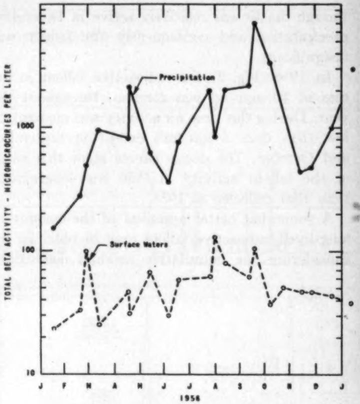

FIG. 4. – A comparison of Cincinnati fallout in rain with the activity of Ohio stream water

Distribution of fallout in cistern water—Early in 1954, an experimental cistern, consisting of a hopper-bottomed tank of 2.62 m³ capacity, was installed to collect precipitation from a portion of the roof of an abandoned home. The cistern was in operation from February 10, 1954 to March 7, 1956, and from July 5 to September 25, 1956. During this period, settled cistern water was withdrawn and tested at frequent intervals while the settled sludge was removed and tested on fifteen occasions. The more significant data from cistern operation are presented in Table 1. The total activity found in the cistern water, sludge, and sludge supernatant are indicated in Col. 7. Sludge supernatant consisted of a known quantity of cistern water (up to 50 l) used to wash the sludge from the cistern bottom. This water was then settled for 10 to 15 minutes and the supernatant removed from the sludge by decantation. The sludge contained loose shingle stone which had been washed into the cistern. It was separated from the sludge and samples of the supernatant, sludge, and roof stone were tested for beta radioactivity. The sludge and supernatant solids found in the roof drainage varied from 9 to 71 with an average of 30 ppm of dry solids of which 30 pct were volatile.

During the sixteen-month period of cistern operation, a total of 50.4 μc of beta activity (Col. 8) from bomb debris ten to 300 days old was estimated to be in the cistern rain. Of this total, 43.95 μc or 87 pct was recovered from the cistern. The remaining 13 pct represents activity fixed to the asphalt roof shingles and errors in measurement. Estimations based on the activity found on washed shingle stone separated from the cistern sludge accounted for much more than the 13 pct. However, since the stones tested were bathed in radioactive rain for days or weeks they may have adsorbed more activity than would shingle stones during roof runoff.

The soluble activity in the cistern water varied from 14 to 56 pct or a weighted average of 48 pct of the total. There seems to be no clear-cut relationship between the percentage of dissolved activity and the age of bomb debris. This is contrary to the observation made in 1953 [*Nader* and others, 1954] that the percentage of dissolved activity in the rain was less for activity of short half-life. Other factors, such as the presence of inert material in the fire ball, the abundance of local non-radioactive air pollutants, the time of exposure of radioactive particles to moisture, and possibly the inflow of radioactive contaminants of different chemical characteristics from the stratosphere to the rainout zone, probably play a role in forming the soluble fraction.

[a] 1956 except as shown.

The concentration of dissolved activity in cistern water varied from 7 to 4160 or an average of 332 μμc/l. Lower values (less than 76 μμc/l) were observed during periods when the bulk of the activity was estimated to be older than 100 days, whereas for activity 7 to 98 days in age, the dissolved activity was 157 μμc/l or more. The percentage of activity associated with the suspended solids ranged from one to 77 pct, with an average of about 25 pct.

In summary, the cistern study reveals that slightly more than half of the activity found in the cistern water was soluble and that up to a third of the activity would be associated with the suspended solids. Over two thirds of the insoluble activity settles as a sludge (1.5 kg dry weight) having an activity of 10 μc/kg (dry weight). Septicity resulted in further solution of activity, but diffusion into the cistern water was minimal when the sludge was undisturbed.

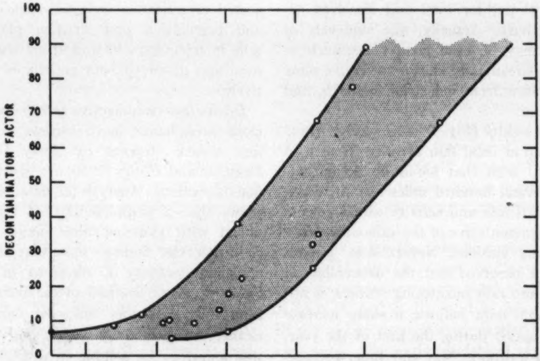

FIG. 5 – The decontamination of rain by natural agencies

The distribution of fallout in surface waters—Nine grab and seven composite (seven- to ten-day) samples from 13 stations on the Ohio River from Pittsburgh, Pennsylvania, to Louisville, Kentucky, were collected between December 27, 1955 to April 20, 1956 in a cooperative study with the Ohio River Valley Water Sanitation Commission. The maximum beta activity found was 100 $\mu\mu$c/l as compared to an arithmetic average value of 27.5 $\mu\mu$c/l of which 15 $\mu\mu$c/l was in solution.

Through the courtesy of F. H. Waring, Chief Sanitary Engineer, Division of Sanitary Engineering, Ohio State Board of Health, the results of additional samples collected from surface streams tributary to the Ohio River are included in Table 2 and Figure 4. The maximum average activity levels of the surface waters of the Little Miami, the Great Miami, and Scioto Rivers are compared with the SEC Cincinnati rainout results for collections made between river samplings.

The stream water results show a maximum dissolved activity of 89 $\mu\mu$c/l compared to a maximum total (suspended and dissolved) activity of 217 $\mu\mu$c/l for tests in 1956. The average total activity for each sampling date fluctuated from 25 to 130 $\mu\mu$c/l depending to some degree on the activity of the more recent rains. The yearly geometric average total and dissolved beta activity of stream water was 50 and 27 $\mu\mu$c/l, respectively, as compared to 974 $\mu\mu$c/l total and 389 $\mu\mu$c/l dissolved activity for Cincinnati rain. The average removal by natural agents is therefore 95 and 93 pct for total and dissolved activity, respectively. Actually, the removals of rain activity may be even greater inasmuch as some of these streams are known to receive some radioactive wastes from industrial, research, and medical facilities.

The plotted results (Fig. 4) more clearly define the relationship of total rain activity (from Cincinnati fallout) with that found at stream stations up to several hundred miles distant. Obviously, Cincinnati rain and activity measurements may not be representative of the rainout at some of these stream stations. Nevertheless, general trends may be observed and the desirability of establishing more rain monitoring stations is apparent. The rain data indicate a sharp increase (150 to 2100 $\mu\mu$c/l) during the first of the year, then, following a drop in May and June, a second rise to levels of 2000 to 7000 $\mu\mu$c/l by September. During the last three months of the year, the rain activity decreased. The lower levels of rain activity usually correspond to longer-lived bomb debris and high levels correspond to young (rapidly decaying) fission products.

The ratio of total rain activity to total surface water activity was determined for each month and reported in terms of the decontamination factor (rainout or fallout activity divided by the surface water activity). These decontamination values were plotted against the rain activity as shown in Figure 5. It will be seen that removal of radioactivity by natural agents increases with increased activity of the rain. Comparable in many respects with other pollutants, the plotted values indicate the application of the law of diminishing returns, that is, high decontamination factors in order of 65 to 90 (98.5 to 98.9 pct removal) for relatively young bomb debris and decontamination factors of 5 to 10 (80 to 90 pct removal) for lower-level longer-lived activity.

The Cincinnati rainout and cistern studies have been combined with the Ohio State stream data for comparison of the distribution of radioactive rainout. The rainout (corrected for decay to the end of a cistern sampling period), the cistern water activity of series 11 to 15 (Table 1), and the activity of stream waters of appropriate date are summarized in Table 3. The table shows that subsidence in the cistern and adsorption by roof shingles results in an average loss of 38.5 pct of the total and 20.6 pct of the dissolved rain activity, whereas the low activity found in stream waters indicates that radioactive particles adsorbed on surfaces, such as vegetation and soil, and percolation and dilution play important roles in achieving a 92 and 91 pct reduction of the total and dissolved beta activity of rain, respectively.

Discussion—Radioactive fallout has been under close surveillance since nuclear weapons were first tested. Reports by *Libby* [1956ab], and *Eisenbud* and *Harley* [1956] are based on gummed film collections. Analysis of data by *List* [1956] shows that a preponderance of the fallout obtained with gummed films occurs during precipitation. Our findings show that about one-half of fallout activity is dissolved in rain water. Similarly about one-half of the activity collected from dust collectors following Operation Hurricane, as reported by *Russell* and others [1955] was found to be soluble in distilled water and dilute salt solutions. The fraction of the total activity which is dissolved or soluble depends on many factors such as the age and particle size of the bomb debris and the adsorptive capacity of local atmospheric dust with which it comes in contact before or during rainout.

Although significant radioactive dustfall of the larger particles may occur in the vicinity of a nuclear test site the finer particles are removed from the air by rainout or snowout and, to a lesser degree, by the impingement of particles on leaves, grasses, and other solid surfaces by wind action. A comparison of the estimated $m\mu c/m^2$ of strontium fallout from rain collections at Cincinnati, Ohio, New York City, New York, [*Harley* and others, 1956], and Milford Haven, England [*Stewart* and others, 1956] is as follows:

Year of deposition	Cincinnati, Ohio	New York, New York	Milford Haven, England[a]
1953	1.22	...	...
1954	1.46	2.88	1.15[b]
1955	2.46	3.35	2.65
1956 (1st half)	2.8	6.67	0.5[c]
1956 (2nd half)	3.07	...	...

[a] The Milford Haven results (HP/R 2017) are reported in units 1000 times higher but the concentration in rain water and a subsequent discussion of these results (HP/R 2056) verifies the correctness of the $m\mu c/m^2$ unit.

[b] May through December.

[c] January through March.

Agreement in fallout values is surprisingly good for the three stations in 1954 and 1955. Disagreement of values for the first five or six months of 1956 may be expected from the known variations in weather patterns with respect to the presence of radioactive air masses prior to more uniform distribution with time. This was clearly demonstrated in Cincinnati during December 1955 when air activity was relatively high but, since no precipitation occurred, the fallout was negligible.

In order to determine the variation in fallout or its distribution over grazing or farm land many more collectors will be necessary. Many rain collectors should be satisfactory, such as the 13.5-inch bucket used, the eight-inch pot *Harley* and others [1956] used in New York or the 0.22 m^2 polyethylene funnel and bottle used at Milford Haven [*Stewart*, 1956]. In continuous use each will collect true dust-fall and secondary aerosols (from previous rainout) as well as rainout and snowout. Depending on wind protection the efficiency with which snow samples will be collected may vary. Studies at Cincinnati by *Nader* [in press] show that a polyethylene waste basket having a diameter of 7.75 inches was as effective in retaining dust as similar containers provided with baffles or wetted with water during periods when the rain had evaporated. The dry solids of rain became attached to the container. Since it is the rain which contains the significant radioactive fallout, this, or a similar container lined with a polyethylene bag, would be a simple and satisfactory fallout collector.

Because most of the activity does not appear in runoff it may be presumed that the radioactivity remains on solid surfaces such as grasses, crops, and soil where, although not presenting a significant external radiation field, it may, at greatly increased levels, present an internal exposure problem via the food chain.

Summary—Fallout radioactivity, largely as precipitation, has been monitored continuously at Cincinnati, Ohio, since the spring of 1953. Rain, cistern, and surface waters were tested to determine distribution and characteristics of the radioactivity.

During the two years of continental testing (1953 and 1955), the predominant air contaminants were characterized as young fission products. The deposition of activity from rain was variable and occasionally quite high. The monthly residual fallout (corrected for decay) reached a maximum of about one microcurie per square meter of surface area on June 1, 1953, and again on June 1, 1955.

In 1954 and 1956 when the air contaminants were of longer half-life the maximum monthly residual was about 0.1 $\mu c/m^2$ in 1954 and 0.4 $\mu c/m^2$ in 1956. It is estimated that on July 1, 1957, the residual activity from fallout during 1953, 1954, 1955, and 1956 was 10, 12, 50, and 105 $m\mu c/m^2$, respectively, or a total of 177 $m\mu c/m^2$ of fission products (nine months to four years of age). The strontium^{90} (yttrium^{90}) deposition at Cincinnati for the four years is estimated to be 11 $m\mu c/m^2$ or an average concentration in rain of 3 $\mu\mu c/l$.

Depending on the time of contact with water, the age of contamination, and other factors, a variable percentage of the total activity (average of 40 to 50 pct) is dissolved in rain water. About 40 pct of the total activity settles out from cistern water. The activity of local surface streams indicates that over 90 pct of the dissolved and total activity in the rain has been removed.

Somewhat less than half of the total activity in surface water was in a dissolved state.

Since so little of the rainout activity can be accounted for as runoff it may be presumed that the radioactive fallout is fairly firmly fixed near its point of deposition as particles or by adsorption on solid surfaces such as vegetation and soil.

Uranium and Radium in the Ground Water of the Llano Estacado, Texas and New Mexico

F. B. BARKER AND R. C. SCOTT

Abstract—Water samples were collected from 47 wells and springs in the Ogallala formation in the Llano Estacado section of the High Plains, Texas and New Mexico. The Ogallala, a fluviatile geologic terrane, is hydrologically and geologically isolated in this region, therefore, the observed radiochemical concentrations are considered as inherent characteristics of the formation in this area. The uranium concentrations ranged from 0.9 to 12 parts per billion (ppb) (median 6.2 ppb), and the radium concentrations ranged from < 0.1 to 0.8 micromicrocuries per liter (median 0.1 $\mu\mu$c/l). The uranium concentrations show a tendency to correlate with the gross chemical character of the waters in accordance with the expected chemical behavior of uranium. The departure of the radium-uranium ratios in all samples from radioactive equilibrium value is explained on the basis of carbonate-complexing of uranium and selective adsorption of radium by minerals having a capacity for base exchange.

Introduction—An investigation of the occurrence of uranium and radium in the ground water in the Ogallala formation in the Llano Estacado (Staked Plain) of Texas and New Mexico was made as part of a comprehensive investigation of the occurrence and history of radioelements in ground waters in various geologic terranes of the United States. A greater insight into the hydrogeochemistry of the radioelements is sought. Understanding the behavior of these elements may lead ultimately to their use in more intensive studies of some of the processes of ground-water geology and hydrology.

The Llano Estacado, about 35,000 sq mi in area, was selected for this initial study because there the most important aquifer, the Pliocene Ogallala formation, is geologically and hydrologically isolated from other formations except for surficial Quaternary deposits, and for the relatively impermeable bedrock floor of older rocks upon which the Ogallala rests. The chemical characteristics of the ground water in the Ogallala, therefore, reflect essentially the inherent characteristics of that formation, somewhat modified by the overlying Quaternary deposits.

Geology and hydrology of the area—The Ogallala formation is a remnant of an extensive fluviatile deposit which was laid down east of the Rocky Mountains province of Colorado and the limestone ranges of central New Mexico during Pliocene time. This formation is composed mainly of silt and fine sand; however, coarse sand and gravel are present throughout. The coarser facies occur principally in broad valleys in the sub-Ogallala floor. Zones of lime-cemented caliche are common throughout the formation, and at a few horizons discontinuous beds of volcanic ash are intercalated in the finer grained sediments [*Theis*, 1936]. A caliche caprock at the top of the Ogallala has a thickness ranging up to several tens of feet.

The caprock is overlain by wind-blown material, much of which was laid down in Pleistocene lakes and ponds. These sediments and the eolian deposits of Recent age are chiefly calcareous and gypsiferous silt, sand, bentonitic clay, and volcanic ash but include local thin beds of fresh-water limestone and diatomite [*Evans* and *Meade*, 1944].

The Llano Estacado is bounded by erosional escarpments on the east and west and by the Canadian River on the north. On these three sides the Ogallala formation and the underlying Cretaceous and Triassic rocks are exposed. To the south the Llano Estacado merges into the Edwards plateau (Cretaceous rocks), but there seems to be no movement of ground water from the Edwards plateau to the Ogallala formation. Both the surface of the present-day plain and the base of the Ogallala formation, as well as the water table lying about halfway between them, slope east-southeastward at an average of about ten feet per mile. When hydrologic equilibrium existed prior to today's intensive pumping for irrigation, the recharge and discharge in the natural hydrologic cycle is estimated to have averaged between 75,000 and 150,000 ac ft yearly. Ground water moved through the formation east-southeastward at an estimated average rate of 200 to 300 feet per year [*White*, *Broadhurst*, and *Lang*, 1946].

Most wells in the Ogallala formation yield water of relatively good quality. Recharge is derived entirely from precipitation on the surface of the

[a] Percentage of total cations, based on equivalents per million (epm).

[b] This sample also contained 0.07 epm carbonate ion.

[c] Percentage alkali metals and total dissolved solids concentration determined on composite sample from four municipal wells of city of Canyon. All of these wells are of similar depth and obtain water from Triassic rocks.

[d] These wells probably draw water from two or more formations.

plain. On the average, only a small fraction of an inch of the annual rainfall reaches the ground-water body. It is believed that there is little, if any, upward leakage of the highly mineralized water in the underlying Cretaceous and Triassic rocks into the Ogallala formation.

Scope of sampling network—Figure 1 shows the locations of the sampling sites. Samples of water from 47 wells and springs in the Ogallala formation of the Llano Estacado were collected and analyzed. Four samples of water from the older formations and three samples from wells supplied by two or more formations also were collected and analyzed for comparison. A description of the source, radium and uranium concentrations, and other pertinent data for each sample are given in Table 1. Uranium concentrations are in parts per billion, radium concentrations are in micromicrocuries per liter and bicarbonate concentrations are in equivalents per million.

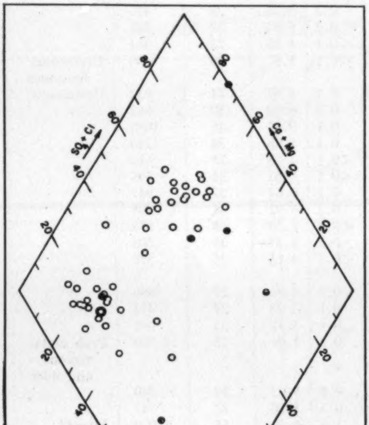

FIG. 2 – Classification of ground water from the Llano Estacado according to its chemical character

Chemical character of the samples—The samples of ground water from the Ogallala may be divided into two groups having slightly different chemical characters. Those from the northeastern part of the Llano Estacado have a much higher percentage concentration of bicarbonate ion, based on equivalents per million, than those from the southwestern part.

The differences in the chemical character of the two groups are illustrated in Figure 2. The chemical character of each sample is shown by the percentages of the major chemical constituents in the total ionic content.

Probably most of the recharge from precipitation reached the Ogallala via the overlying Quaternary deposits, and differences in the chemical character of the two groups reflect differences in the composition of the Quaternary deposits in different areas on the plain. The high-bicarbonate water represents chemical leaching of the lacustrine material in which silt, sand, and volcanic ash predominate. The area from which the samples of water high in sulfate and chloride were collected is adjacent to the Pecos River basin in New Mexico. Large exposures of gypsiferous materials and other evaporites are found in this river basin and other areas in southern New Mexico. The prevailing winds from the west remove gypsiferous and saliferous dust from southern New Mexico and deposit it in depressions on the southern part of the Llano, after which sulfate and chloride salts are carried into the underlying formations and to the ground-water reservoir by percolating meteoric water.

Uranium content of the waters—All samples were analyzed for uranium content by the fluorimetric method [*Thatcher* and *Barker*, 1957]. The concentrations of uranium in water from the Ogallala formation ranged from 0.9 to 12 parts per billion (ppb) with a median of 6.2 ppb. These concentrations are relatively high compared to the uranium content of 67 random samples from fluviatile sedimentary aquifers throughout the United States. The uranium concentration in these random samples ranged from <0.1 to 22 ppb with a median of 1.6 ppb.

The areal distribution of the uranium concentrations in the samples from the Ogallala are shown by an isogram map, Figure 3. A trend of increasing uranium content in the water seems to coincide with the general direction of ground-water movement.

The downgradient increase in uranium content probably is a result of the water at successive downgradient locations having been in the aquifer longer than water obtained from upgradient sources. Local variations in chemical character and content of radioelements probably reflect the effects of the increments of recharge from nearby playas and other depressions whose bottoms are permeable enough to permit recharge to the Ogallala. Such areas commonly contain highly mineralized zones of evaporites, probably including some uranium salts. These materials may be dissolved by the percolating waters and thereby create local anomalies in the chemical character of the ground water. The two sources from the Ogallala formation having the highest uranium content, 43 and 51 in Table 1, are somewhat anomalous and possibly represent notable examples of such a situation.

The uranium concentrations tend to correlate with the total dissolved solids in the waters, as is shown in Figure 4. Again, two distinct groups of plotted points are observed which correspond to the groups of high and low bicarbonate percentage composition shown in Figure 2. The correlation index for the high-bicarbonate group is 0.7 and that for the low-bicarbonate group is 0.6, which indicate definite trends. These trends are consistent with the theoretical considerations of the solution of soluble substances.

Another tendency toward correlation is shown by a plot of uranium concentration against bicarbonate concentration, Figure 5. The coefficient of correlation between these variables is 0.6. This relationship probably is the result of the formation of the very stable, soluble, anionic, uranyl-carbonate complexes which are formed according to the following equations

$$HCO_3^- \rightleftharpoons H^+ + CO_3^= \tag{1}$$

$$UO_2^{++} + 2CO_3^= + 2H_2O \rightleftharpoons UO_2(CO_3)_2(H_2O)_2^= \tag{2}$$

$$UO_2^{++} + 3CO_3^= \rightleftharpoons UO_2(CO_3)_3^{-4} \tag{3}$$

Applying the law of mass action to these equations shows that an increase in the concentration of bicarbonate ions tends to decrease the concentration of the uranyl ions through the formation of the uranyl-carbonate complexes. A decrease in concentration of uranyl ions enhances any mechanism by which uranyl ions come into solution. The formation of aqueous uranyl ions is probably one step in most processes whereby uranium is dissolved from pre-existing uranyl compounds or other uranium species existing in the solid phase in the formation. Therefore, the solvent power of the water for uranium is increased with increasing bicarbonate content.

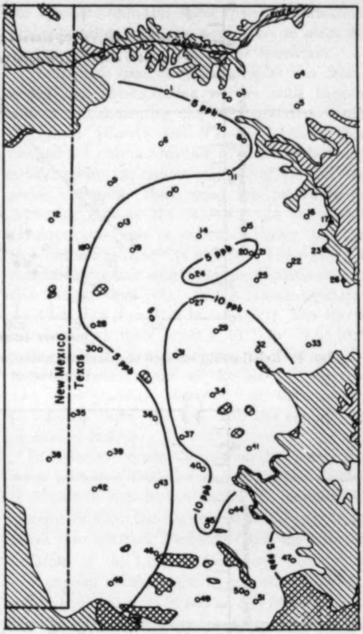

FIG. 3 – Isogram lines of uranium concentration in the ground water of the Llano Estacado (see Fig. 1)

Radium content of the waters—In the course of its radioactive decay, uranium gives rise to a series of other radioactive nuclides, including radium^{226}, as follows: $U^{238} \xrightarrow{(4.51 \times 10^9 y)} Th^{234} \xrightarrow{(24.1d)} Pa^{234} \xrightarrow{(1.14m)} U^{234} \xrightarrow{(2.67 \times 10^5 y)} Th^{230} \xrightarrow{(8.0 \times 10^4 y)} Ra^{226} \xrightarrow{(1620y)}$ other daughter nuclides. The times indicated are the half-lives of the nuclides undergoing each transformation [*Kirby*, 1953, p. 17]. The amount of any member of such a series present in a closed system containing one or more of its precursors may be calculated by a method devised by *Bateman* [1910]. For radium^{226} and for any time greater than ten years, this method gives rise to the expression

$$Ra_t^{226} = (3.41 \times 10^{-7} \exp[-1.54 \times 10^{-10} t] - 4.9 \times 10^{-7} \exp[-2.6 \times 10^{-6} t] + 1.5 \times 10^{-7} \exp[-8.7 \times 10^{-6} t]) U_0^{238} + (8.4 \times 10^{-3} \exp[-2.6 \times 10^{-6} t] - 8.5 \times 10^{-3}$$

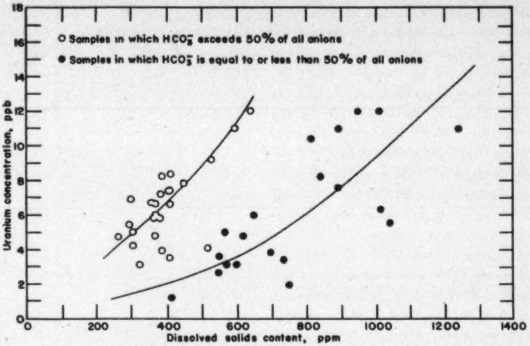

FIG. 4 – Relationship between uranium concentration and dissolved solids content of water from the Ogallala formation of the Llano Estacado

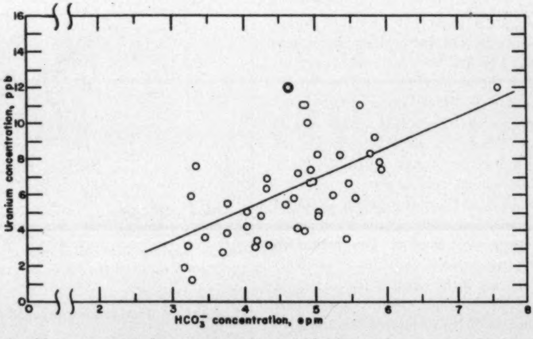

FIG. 5 – Relationship between uranium concentration and bicarbonate ion concentration in water from the Ogallala formation of the Llano Estacado

$$\exp[-8.7 \times 10^{-6}t] + 1.23 \times 10^{-4} \exp[-4.28 \times 10^{-4}t]) (Th_0^{234} + Pa_0^{234} + U_0^{234}) + 2.0 \times 10^{-2} (\exp[-8.7 \times 10^{-6}t] - \exp[-4.28 \times 10^{-4}t]) Th_0^{230} + \exp[-4.28 \times 10^{-4}t] Ra_0^{226}$$

where Ra_t^{226} = weight of radium^{226} at time t
U_0^{238}, Th_0^{234}, etc = weight of uranium^{238}, thorium^{234}, etc. at time zero
t = elapsed time from any arbitrary zero

As the time becomes very large, the above equation reduces to

$$Ra_t^{226} = 3.41 \times 10^{-7} U_0^{238} \exp[-1.54 \times 10^{-10}t] = 3.41 \times 10^{-7} U_t^{238}$$

indicating that equilibrium is established between the radium and the uranium. The time required for this equilibrium to be attained depends upon the initial concentrations of the various nuclides intermediate between uranium and radium. If significant quantities of any of the substances involved are added or removed from the system, radioactive equilibrium would not be established, although another equilibrium involving the rate of addition or removal might be possible.

In any geologic terrane which has been completely isolated, so far as transfer of material is concerned, for one million years (assumed time from beginning of the Pleistocene to the present), the Bateman solution for radium^{226} is

$$Ra^{226} = 3.05 \times 10^{-7} U_0^{238} + 6.20 \times 10^{-4} (Th_0^{234} + Pa_0^{234} + U_0^{234}) + 3.42 \times 10^{-6} Th_0^{230}$$

Uranium^{238} and uranium^{234} are chemically identical; therefore, they would be deposited in approximately the same ratio as they occur naturally, or

$$U_0^{234}/U_0^{238} = 5.7 \times 10^{-5}$$

Thorium^{234} and protactinium^{234} occur in such small quantities compared to uranium^{238} that even if there were a million-fold enrichment during deposition, the effect upon the radium content would be negligible. It is difficult to achieve an enrichment of this magnitude in one step even in the laboratory using the most favorable methods; therefore, it is probably not often achieved in nature, and these intermediate nuclides may be neglected. An approximate expression is then

$$Ra^{226} \approx 3.4 \times 10^{-7}\ U_0^{238} + 3.4 \times 10^{-6}\ Th_0^{238}$$

or

$$Ra^{226} \approx (3.4 \times 10^{-7} + 6.1 \times 10^{-11}k)\ U_0^{238}$$

where

$$k = Th^{230} \text{ enrichment factor} = \frac{\text{ratio of } Th^{230} \text{ to } U^{238} \text{ deposited}}{\text{radioactive equilibrium ratio of } Th^{230} \text{ to } U^{238}}$$

Thus, regardless of initial conditions, the radium^{226} must be present approximately in equilibrium with the uranium or in excess as determined by the thorium^{230} enrichment during deposition.

The ratio of radium^{226} to uranium in waters from a formation may indicate something of the history of or conditions in the formation, but the two elements differ widely in chemical behavior and the amounts found in water from the formation probably never have the same ratio as amounts existing in the solid state in the formation.

The radium content of the samples was determined by coprecipitating radium with barium sulfate and measuring the alpha-activity of the precipitate [*Barker* and *Thatcher*, 1957]. This method not only is sensitive to radium^{226} but also is affected by the radium member of the thorium series, radium^{224}. Thus, using this procedure to determine radium, the values of the radium-to-uranium ratios may be somewhat higher than the true ratio of radium^{226} to uranium. The measured radium contents in water from the Ogallala formation ranged from <0.1 to 0.8 micromicrocuries per liter with a median of 0.1 $\mu\mu c/l$. The Ra/U ratios ranged from $<0.8 \times 10^{-8}$ to 19×10^{-8} microcuries Ra per microgram U. The radioactive equilibrium value of the Ra^{226}/U ratio is 34.1×10^{-8} $\mu c/\mu g$; therefore, all the samples of Ogallala water had less than the equilibrium amount of radium.

In order to explain the radium deficiency, one must postulate that the radium in the aquifer is present in less than its radioactive equilibrium amount or that the uranium is being selectively taken into solution. Because of the age and the isolation of the Ogallala formation, equilibrium or a radium excess should have been established, unless large amounts of ionium had been removed during Pleistocene time or large amounts of radium had been removed during Recent time. The only mechanism for this removal would be

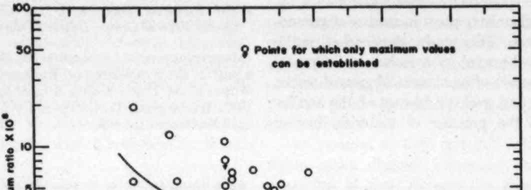

FIG. 6 – Relationship between the radium-uranium ratio and percentage of alkali metal ions in water from the Ogallala formation of the Llano Estacado

by ground-water discharge along the eastern escarpment. Such loss of radium is very minor today and probably was relatively minor during both Recent and Pleistocene times. In addition, the chemistry of ionium is such that it is not likely that large amounts would be removed by ground water from the formation.

A more reasonable explanation for the radium deficiency in the ground water might be ion exchange. If the radioelements in the formation occur in a certain ratio, the uranium and radium should be available for solution in that same ratio. However, as soon as they entered the solution phase, much of the uranium would be complexed by the carbonate ions present and would appear in an anionic form. These anionic complexes would not be subject to adsorption by cation-exchange mechanisms, whereas the uncomplexed radium cations could be adsorbed by clays and other minerals having cation-exchange capacity. The ground water would then contain an excess of uranium over radium, as was observed.

Some supporting evidence for this hypothesis is obtained from a plot of the radium-uranium ratio against the percentage of alkali metals (based on equivalents per million) present in solution as shown in Figure 6. The correlation index of 0.45 suggests a possible relationship between the two variables. If an increase in alkali metal ion percentage is taken as an indication of the occurrence of ion-exchange, the decrease of the radium-uranium ratio may be logically suggested to be a result of the same process.

Conclusion—Radioelement determinations used with ordinary chemical analyses will enhance the part that geochemistry plays in studies of groundwater resources. This study shows that radioelements may be used to corroborate inferences as to the direction of movement of ground water, the lithology and geologic history of the aquifer material, and the presence of materials having ion-exchange capacity. It is apparent that tentative geochemical conclusions reached in this investigation may be refined by further work; specifically recommended is sampling of formational water at known horizons in the Pleistocene lacustrine deposits and determinations of radium in clay samples from both the Ogallala and the Pleistocene sediments.

Disposal of Radioactive Waste on Land

H. H. HESS AND W. R. THURSTON

Abstract—Two years' consideration of the disposal problem by the National Research Council Committee on Waste Disposal has led to certain conclusions which are presented. Waste may be safely disposed of at many sites in the United States but conversely there are many large areas in which it is unlikely that disposal sites can be found as, for example, the Atlantic seaboard. The research to ascertain feasibility of disposal has for the most part not yet been done. The most practical immediate solution of the problem suggests disposal in cavities mined in salt beds or domes. Disposal could be greatly simplified if the waste could be gotten into solid form of relatively insoluble character. Disposal in porous beds underground has capabilities of taking large volumes but will require considerable research to make the waste compatible with such an environment. The main difficulty with this method at present is to prevent clogging of pore space as waste is pumped in.

Summary—A committee of geologists and geophysicists was established by the National Academy of Sciences-National Research Council at the request of the Atomic Energy Commission to consider the possibilities of disposing of radioactive wastes within the continental limits of the United States. The group was charged with assembling the existing geologic information pertinent to disposal, delineating the unanswered problems associated with the disposal schemes proposed, and point out areas of research and development meriting first attention; the committee is to serve as continuing adviser on the geological and geophysical aspects of disposal and the research and development program.

The Committee with the cooperation of the Johns Hopkins University organized a conference at Princeton in September 1955. After the Princeton Conference members of the committee inspected disposal installations and made individual studies. Two years' consideration of the disposal problems leads to certain general conclusions. The research to ascertain feasibility of disposal has for the most part not yet been done. A preliminary report has been published [*Committee on Waste Disposal*, 1957].

Wastes may be disposed of safely at many sites in the United States but, conversely, there are many large areas in which it is unlikely that disposal sites can be found, for example, the Atlantic Seaboard.

Storage in tanks is at present the safest and possibly the most economical method of containing waste.

Disposal in salt is a very promising method for the near future. Research should be pushed immediately on the structural problem of stability with respect to size of cavities at a given depth; on the thermal problem (getting rid of the heat or keeping it down to acceptable levels); and on the economics of such disposal.

Also very promising is the stabilization of the waste in a slag or ceramic material forming a relatively insoluble product. This could be placed in dry mines, surface sheds, or large cavities in salt.

In the future the injection of large volumes of dilute liquid waste into porous rock strata at depths in excess of 5,000 feet may become feasible but means of rendering the waste solutions compatible with the mineral and fluid components must first be developed. The pumping of wastes into porous beds interstratified with impermeable formations in a synclinal structure is an interesting possibility for disposing of the large volumes of wastes to be expected in the future. The composition of the rocks and the connate waters are both variable as will be the composition of the waste solutions so an almost infinite variety of circumstances result. The problem would have to be solved first for a given bed at a given site for a given waste solution at a given dilution.

The removal of Cs^{137} and Sr^{90} from the waste would make disposal somewhat easier for the waste free of these isotopes but does not change qualitatively the recommendations made in the report.

Continuing disposal even of low level waste in the vadose water zone is of limited application and probably involves unacceptable long-term risks.

In the complex relation between (a) storage time of waste for cooling, (b) transportation cost in shielded carriers, and (c) distance to disposal site, the last of these factors must be considered before locating any plant which produces large quantities

of waste, remembering that there are large sectors of the country where disposal is not possible.

The movement of gross quantities of fluids through porous media is reasonably well understood by hydrologists and geologists, but whether this is accomplished by forward movement of the whole fluid mass at low velocity or whether the transfer is accomplished by rapid flow in "ribbons," is not known. In deep disposal of waste in porous media it will in many cases be essential to know which of these conditions exists. This will be a difficult problem to solve.

The education of a considerable number of geologists and hydrologists in the characteristics of radioactive wastes and its disposal problems is going to be necessary.

Fitting a Generalized Log-Normal Distribution to Hydrologic Data

D. L. BRAKENSIEK

Abstract—A statistical distribution is developed which makes it possible to fit a wide range of positively skewed hydrologic data. It is shown that the general least-squares fitting equations will reduce to simple forms for fitting a normal, log-normal or extreme-value distribution to data. Two fitting processes are developed for fitting data by the so-called generalized log-normal distributions. Examples are given for illustrating the fitting procedures.

Introduction—Three statistical distributions currently find wide use in hydrologic frequency analyses, that is, the normal, log-normal, and extreme-value distributions. It is the purpose of this paper to develop a generalized log-normal statistical distribution. This general frequency distribution would tend to unify the frequency-analysis problem for the hydrologist and at the same time give him a more versatile tool.

Basic in the development of a generalized log-normal distribution was the idea of a modified log-normal distribution which was mentioned by *Hazen* [1930]. Also, a recent investigation by *Chow* [1954] on the skew factors of a log-normal distribution was important in its development. Following the formulation of the frequency distribution, least-squares fitting equations are presented. Included as special cases are simple least squares fitting equations for the normal, extreme-value, and log-normal distributions. A slightly more laborious least-squares fitting procedure is presented for other positively skewed distributions.

Examples utilizing the least squares fitting equations are given. Examples include one each for the normal, log-normal, and extreme-value distributions, and one considers the case in which no specific distribution is assumed. While the latter case reduces to a pure curve fitting exercise it may be justified in certain cases as an expediency.

Symbols—The following symbols are used.

x	observed variate
U	transformed variate
$\bar{x}$, $\bar{U}$	mean of the set of each variate
K	frequency factor
C_v	coefficient of variation of the set of x variates
CV	coefficient of variation of the set of U variates
z	standardized normal deviate
n	number of observed variates
m	order number of each variate when they are first ranked in decreasing order.

Formulation of distribution—As pointed out by *Chow* [1951] a hydrologic variable, for example, annual peak runoff rates, may be related to its parent frequency distribution by the equation

$$x/\bar{x} = 1 + C_v K \qquad \text{(1a)}$$

or

$$x = \bar{x} + \bar{x} C_v K \qquad \text{(1b)}$$

Making the assumption that the x variable may be transformed to a log-normal variate leads to a new frequency equation for the transformed variate U

$$U/\bar{U} = 1 + CV\,K \qquad \text{(2)}$$

Eq. (2) is related to (1a) by the linear transformation

$$U/\bar{U} = k(x/\bar{x}) + (1 - k) \qquad \text{(3)}$$

where $k = (CV/C_v)$. From *Chow's* [1954] investigation the right-hand side of (2), since U by hypothesis is a log-normal variate, can be written

$$1 + CV\,K = \exp\,[bz - (b^2/2)] \qquad \text{(4)}$$

where

$$b = \sqrt{\ln\,(1 + CV^2)}$$

and z is the standardized normal deviate. Combining (2) and (4) leads to the frequency distribution of U, a generalized log-normal variate

$$U/\bar{U} = \exp\,[bz - (b^2/2)] \qquad \text{(5)}$$

in which z is the independent variable.

In the usual manner, least squares fitting equations for the U-distribution are found to be

$$\hat{k} = \exp\,(-b^2/2)\;[\Sigma(x/\bar{x} - 1)\exp\,(bz)/\Sigma(x/\bar{x} - 1)^2] \qquad \text{(6a)}$$

and

$$\hat{b}^2 + 2\hat{b}/n[\Sigma z^2 + \Sigma\,\ln\,(U/\bar{U})] = 2/n\,\Sigma z\ln U \qquad \text{(6b)}$$

To be of practical use the solutions of (6a) and (6b) or both must be obtained by routine computational procedures. The following section will consider this requirement in some detail.

Computational procedures—The normal and extreme value distributions are simply fitted to data by using an adaptation of (6a). This adaptation requires the first two terms of the expansion of $\exp\,(bz) = 1 + bz + \cdots$ and the identity $b = CV$. These approximations are sufficiently accurate for values of CV up to $CV = 0.45$. Recalling the definition of k, (CV/C_v), and substituting the above approximations into equation (6a) one obtains

$$\bar{x}C_v = \exp(CV^2/2) \sum(x - \bar{x})^2/\sum xz \quad \text{(7a)}$$

For a normal distribution one has $CV = 0$. Hence a least-squares fit of that distribution to data would follow from the equation

$$\bar{x}C_v = \sum(x - \bar{x})^2/\sum xz \quad \text{(7b)}$$

where the values of z are read from a table of areas of the normal distribution.

For an extreme value distribution *Chow* [1954] has shown that $CV = 0.364$. Hence the least squares fitting equation would be

$$\bar{x}C_v = 1.067\ (\sum(x - \bar{x})^2/\sum xz) \quad \text{(7c)}$$

A log-normal distribution postulates that $k = (CV/C_v) = 1$. Hence (6b), for the least squares fit of a log-normal distribution to data, becomes a cubic equation in $\hat{b}$

$$\hat{b}^3 + 2\hat{b}/n(\sum z^2 + \sum \ln(x/\bar{x})] = 2/n\sum z \ln(x/\bar{x}) \quad \text{(8a)}$$

A satisfactory first approximation for $\hat{b}$ in (8a) follows from

$$b = \sum z \ln x/\sum z^2 \quad \text{(8b)}$$

If the value of b is small, say less than 0.5, then the estimate obtained from (8b) would be satisfactory. The definition $b = \sqrt{\ln(1 + CV^2)}$ allows the calculation of C_v as for this case $C_v = CV$.

For the above three distributions the actual data fitting equation is based on (1b), that is, $x = \bar{x} + \bar{x}\,C_vK$. The value of $\bar{x}$, the mean, is calculated in the usual manner and the value of $\bar{x}C_v$ follows from (7b), (7c), or (8a). Further, the values of K, found in Table 1, correspond to $CV = 0$, $CV = 0.364$ and $CV = C_v$ for the normal, extreme-value, and log-normal distributions respectively. If for each distribution the data is plotted on its respective probability paper, the two arbitrary calculated points, (x_1, K_1) and (x_2, K_2), would fix the least squares line of fit.

In general, for any case that the positive skew, as defined by the identity $CS = 3\ CV + CV^3$, [*Chow*, 1954] can be postulated, (6a) would be computationally feasible. Values of the exponential term, $\exp(bz)$, are tabled in most mathematical handbooks. For cases in which nothing is known of the skew of the parent population, (6a) and (6b) must be solved by other methods. The first method described below would be satisfactory for values of CV less than 0.45. However, even for larger values a workable fit to data would be obtained. The value of this procedure stems from being a quick, visual procedure.

Substituting the value of $\bar{x}C_v$ from (7a) into (1a) one has

$$x = \bar{x} + B \exp(CV^2/2)K \quad \text{(9)}$$

where $B = \sum(x - \bar{x})^2/\sum xz$. Eq. (9) may be used in a simple procedure for obtaining a visual estimate of CV. The procedure would be as follows: (1) Plot the x-data on log-normal probability paper

TABLE 1 – *Theoretical log-probability frequency factors*[a]

[a] Adapted from *Chow* [1954]. Each column of Chow's Table 2 was plotted against CV. Values in this table were then read from these graphs.

using the plotting position formula $m/(n + 1)$. (2) Refer to Table 1, in which values of the frequency factor K for several probability values and for a range of CV's are given. Substitute values of K and the respective CV value into (9) and compute values of x. Then plot these values on the graph of (1) at their respective probability values, which are given at the top of each column. (3) The best visual fit of the calculated points to the observed points would define an estimate of CV.

The following procedure may be used for improving on the value of CV estimated visually or as an independent fitting process. This procedure is not limited by the magnitude of CV. The process would be most conveniently carried out in a tabular form such as is described below. (1) The first three columns of a tabular form would consist of ranked values, in decreasing order, of the observed variable, each plotting position, $m/(n + 1)$, and the corresponding value of the standardized normal deviate z, respectively. (2) Corresponding to the initial estimate of CV, CV_0, column 4 would be filled in with the K-values for each value of the ranked variate. These values would be obtained by the following scheme. From Table 1, pick two values of K from the corresponding CV_0 row, for example, the values of K for probability of 0.01 and 0.95. Corresponding to these two values of K pick off the corresponding two values of z, that is, from the first row of Table 1. On a sheet of semi-log paper plot the two values of $(K + 1/CV_0)$ as ordinate and the respective values of z as abscissa. By the nature of the definition of K [*Chow*, 1954], these two plotted points will uniquely fix a straight line. Now from this graph K-values may be read off for each ranked observation by referring to its z-value. (3) Calculate the simple correlation coefficient r of x on K. For a simpler calculation, one would calculate r^2, that is, $r^2 = [\Sigma(Q - \bar{Q})(K - \bar{K})]^2/\Sigma(Q - \bar{Q})^2 \Sigma(K - \bar{K})^2$. (4) For several other values of CV, above and below the first CV value, perform steps (2) to (3). In this way the value of CV which gives rise to the largest r^2 value can be approximately determined. It will generally happen that over a range of CV values the value of r^2 does not change appreciably. Hence, an approximate 'closest' fitting frequency equation can be obtained without actually 'pin-pointing' the optimum CV-value.

As pointed out, the above procedure is valid for any CV value. In those cases that a frequency analysis is simply a curve fitting problem it would probably have considerable merit. To facilitate bringing together the pertinent formulas for a particular frequency distribution, the following section will spell out procedures for fitting the three common distributions and also for the generalized log-normal distribution.

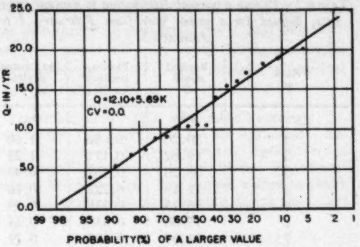

FIG. 1 – Normal distribution fitted to annual runoff

Empirical check of fitting procedures—All of the data utilized in the following cases were collected at the Soil and Water Conservation Research Station, Coshocton, Ohio.

The data used for checking the validity of (7b) for fitting a normal distribution represents annual runoff from Watershed 92. Following are the necessary computations.

By Eq. (7a), $\bar{Q}C_v = \Sigma(Q - \bar{Q})^2/\Sigma Qz = 5.69$.

By definition, $CV = 0$.

The fitted frequency equation, from Eq. (1b) is $Q = 12.10 + 5.69\,K$.

Calculating two points on the fitted line (Fig. 1): (a) Prob. = 0.05, $K = 1.64$; (b) Prob. = 0.95, $K = -1.65$

Substituting the K values into the frequency equation one finds that $Q = 21.4$ plots at 0.05 and $Q = 2.71$ at 0.95.

Table 2 shows computed values and Figure 1 shows the fitted normal distribution and the plotted data.

An extreme-value distribution was fitted to 24 hour maximum precipitation amounts. The calculations involved in solving (7c) are:

By Eq. (7c), $\bar{P}C_v = 1.067\,\Sigma(P - \bar{P})^2/\Sigma Pz = 0.76$.

By definition, $CV = 0.364$.

The fitted frequency equation, from Eq. (1b) is $P = 2.39 + 0.76\,K$.

Calculating two points on the fitted line (Fig. 2): (a) Prob. = 0.05, $K = 1.87$; (b) Prob. = 0.95, $K = -1.30$

Substituting the K value into the frequency equation one finds that $P = 3.81$ plots at 0.05

TABLE 2 – *Fitting a normal distribution to annual runoff data, defined for a water year from February 1 to January 31*

Rank m	Ranked runoff Q	Plotting position $m/(n+1)$	Std. normal deviate z
	in/yr

Sum...............	205.75		
$\bar{Q}$...............	12.1029		

and $P = 1.40$ plots of 0.95. Figure 2 exhibits the data and the fitted distribution. Also included on this graph is the line of fit obtained by the fitting method proposed by *Gumbel* [1954].

A log-normal distribution was fitted to data comprising the runoff during the three month period, April–June, observed on Watershed 92. The computations are: $\sum z \ln Q = 7.471$.

By Eq. (8a), $b = 0.5082$, $CV = 0.543 = C_v$.

By Eq. (8b), $b = 0.5268$, $CV = 0.560$

The fitted frequency equation from Eq. (1b) is $Q = 4.25 + 2.31\,K$.

Calculating two points on the fitted line (Fig. 3): (a) Prob. = 0.05, $K = 1.84$; (b) Prob. = 0.95, $K = -1.14$.

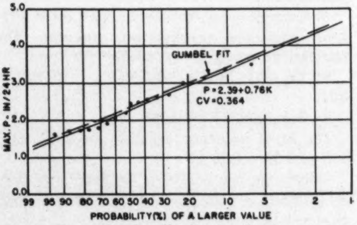

FIG. 2 – Extreme-value distribution fitted to 24-hour maximum precipitation

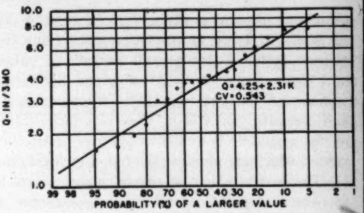

FIG. 3 – Log-normal distribution fitted to April–June runoff

Substituting the K value into the fitted frequency equation one finds that $Q = 8.62$ plots at 0.05 and $Q = 1.62$ plots at 0.95. The fitted distribution is given in Figure 3. It should be noted that (8a) and (8b), for this case, give nearly identical results.

Data to which a generalized log-normal distribution was fitted were annual maximum two-hour runoff amounts. No assumption was made on the amount of skew to assume. However, in actual practice an extreme value distribution might have been assumed. The computations are:

By Eq. (7a), $\bar{x}C_v = 0.1183 \exp(CV^2/2)$.

Visual fitting by Eq. (9), $Q = 0.22 + 0.12 \exp(CV^2/2)K$.

Calculated r^2 values: $r^2(CV = 0.0) = 0.967$; $r^2(CV = 0.1) = 0.973$; $r^2(CV = 0.2) = 0.972$; $r^2(CV = 0.4) = 0.958$.

The fitted frequency equation from Eq. (1b) is $Q = 0.22 + 0.12\,K$.

Points on the fitted curve (Fig. 4) are found in the same manner as in other examples except that more than two values of Q must be calculated in order to fix the curve.

The first step was determining a visual estimate

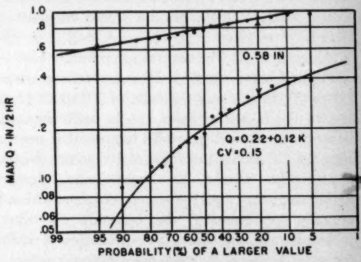

FIG. 4 – Generalized log-normal distribution fitted to two-hour maximum runoff

of CV. This value was determined to be 0.1. The final fit corresponds to a value of $CV = 0.15$. The r^2 value for $CV = 0.15$ was slightly more than the r^2 value for the extreme value CV value. Thus the more logical approach of utilizing a specific distribution would have given essentially the same fit.

Discussion—The numerous developments in frequency-analysis procedures in recent years has made it difficult for the analyst to keep abreast of new methodology. In this respect the generalized log-normal distribution would seem to be of value in that the analyst would not be required to have at hand a number of unrelated fitting procedures. The simple fitting procedure developed for the extreme value distribution would seem to compare quite well with an established fitting procedure and would seem to be simpler to apply.

A point of possible interest is the idea of transforming data so as to be made amenable by a certain distributional theory. For every set of data the determination of the parameter $k = CV/C_v$ fixes a transformation of the observed variates to more nearly log-normal variates. This transformation is given by

$$U = \bar{x}(1/k - 1) + x$$

where x is the original variate and U is the transformed variate. With respect to the example shown in Figure 4, the transformation would have been $U = x + 0.58$. This transformation is shown by the upper curve in Figure 4.

The idea of rectifying skewed frequency data was introduced by *Goodrich* [1927] and has since been recommended as a visual fitting procedure [*Sub-Committee of the Joint Division Committee on Floods*, 1953].

Acknowledgments—This watershed-hydrology research project is maintained by the Agricultural Research Service, U. S. Department of Agriculture, in cooperation with the Ohio Agricultural Experiment Station, Wooster, Ohio. The author wishes to thank J. L. McGuinness for his assistance during the course of this study.

Seismological Studies of the Western Rift Valley of Africa*

GEORGE H. SUTTON AND EDUARD BERG

Abstract—Intensity, strain release, and first-motion studies of earthquakes along the Western Rift Valley of Africa, using data from the seismograph network of the Institut pour la Recherche Scientifique en Afrique Centrale in the eastern Belgian Congo, during the period from May 1953 to April 1956 are presented. Regions of activity shifted during the period of observation, an increase in activity west of Lake Albert in July 1956 being especially noticeable. Intensity maps for three earthquakes show an elongation of isointensity regions parallel to the Rift. The rate of strain release in the area increased with the commencement of the Lake Albert shocks, changing from 35×10^8 ergs$^{1/2}$ to 155×10^8 ergs$^{1/2}$ per 100 days. Strain released during several aftershock sequences was proportional to the logarithm of the time after the initial shock.

First-motions from Rift Valley earthquakes to the stations of the Institut pour la Recherche Scientifique en Afrique Centrale (IRSAC) do not give a unique determination of the predominant type of faulting. The data are consistent with dip slip faulting along steeply dipping faults parallel to known faults in the region with motion such that the elevated areas are being further elevated and the depressed areas further depressed. They are also consistent with strike slip faulting along near-vertical faults with the eastern sides moving north. In agreement with the near station results, first-motion data from distant stations for two shocks west of Lake Albert indicate some combination of reverse dip-slip and sinistral strike-slip motion along a fault plane dipping toward the Rift Valley.

Introduction—The data presented here include (1) intensities and magnitudes; (2) aftershock strain release and regional strain release observations; and (3) first-motion observations of earthquakes in the vicinity of the Western Rift Valley of Africa.

The seismograph network of the IRSAC in eastern Belgian Congo, has been in operation since May 1953, at which time the station at Lwiro was put in operation. At the conclusion of the present study, three stations were operating: Lwiro, Astrida, and Uvira (Fig. 1). These stations form a triangle with sides approximately 120 km in length astride the Western Rift Valley. They have been described previously by *DeBremaecker* [1955]. During the period covered by this study each station was operated with a long and short period Benioff vertical and two short period Wood-Anderson horizontal seismographs.

One of the primary objectives of the IRSAC network is to study the seismic activity associated with the faulting and volcanism of the Western Rift Valley. The present paper includes results of observations in this region during the three-year period from May 17, 1953 to April 1, 1956. Most of the detailed observations were obtained during the period April 5, 1955 to April 1, 1956 when all three stations were in operation.

Earthquake intensities have been determined mainly through questionnaires returned from territorial administrators in the Congo and Ruanda-Urundi under a routine program established by DeBremaecker. Intensity data from British East Africa have been obtained with the cooperation of the East African Meteorological Service and were available for only the last six months covered in this paper. Modified Mercalli scale intensities and Richter magnitudes using the Wood-Anderson torsion seismographs as standard have been used in this study.

Intensity observations—The locations of maximum intensity for reported earthquakes during the period April 6, 1955 to April 1, 1956 are shown in Figure 1. The hachured areas are those from which earthquakes were reported felt during the period May 1953 to April 5, 1955 [*DeBremaecker*, 1955]. The largest earthquakes during the later period occurred west of Lake Albert and east of Lake Tanganyika. These areas were relatively quiet during the earlier period. The effect of the activity in these areas on the regional rate of strain release will be discussed below.

Figure 2 is an isointensity map for the shock of July 22, 1955 near the west shore of Lake Albert. The intensity data from this shock are the most complete of any of the Rift Valley shocks studied to date at IRSAC. The instrumental epicenter and isointensity lines locate the focus near the

rift wall west of Lake Albert. Elongation of isointensity lines parallel to the structure is evident. Maximum intensity was VI Mercalli units and the magnitude recorded at Lwiro was 6.0.

An isointensity map for the shock of September 4, 1955, also near the west shore of Lake Albert, is shown in Figure 3. Again, there is some indication of elongation parallel to the structure for the higher intensity contours although this is not as definite as in the preceding example. There is some offset between the (IRSAC) instrumental epicenter and the region of maximum intensity. The USC&GS epicenter puts the shock on the eastern side of the rift. The intensity data indicate that the IRSAC epicenter is probably more nearly correct and that the faulting was on the western side of the

rift. Maximum intensity for this shock was VI and the magnitude at Lwiro was 6.3.

This and the previous shock have been used in a first-motion study of the nature of faulting, as interpreted from distant station observations by the Byerly-Hodgson method, and will be discussed below.

Figure 4 is an isointensity map for the shock of February 3, 1956 east of Lake Tanganyika near the border between Urundi and Tanganyika Territory. Again, the isointensity lines roughly parallel the structure. The maximum reported intensity was VI. However, there is no closure of the isointensity lines and greater intensities might have been reached further east or south. The magnitude at Lwiro for this shock was 5.5.

Strain release—Following the method of *Benioff* [1951], the square root of the seismic energy J was calculated using the relation $\log J^{\frac{1}{2}} = 4.5 + 0.9 M$, where M is the magnitude. (This equation has been superseded [*Gutenberg*, 1956], but was used here in order to facilitate comparison of our results with those of Benioff.) The summation of the $J^{\frac{1}{2}}$ was plotted against time. Assuming a linear relationship between the energy and the square of the strain, the square root of the energy is proportional to the strain, and a plot of cumulative $J^{\frac{1}{2}}$ against time will give the rate of strain release.

Figure 5 is a plot of cumulative strain release through Rift Valley earthquakes of magnitude 3.0 or greater during the three-year period of observation. Two rates are indicated, 35×10^8 ergs$^{\frac{1}{2}}$/100 days and $155 \times$ ergs$^{\frac{1}{2}}$/100 days. The higher rate is a reflection of the increased activity west of Lake Albert and east of Lake Tanganyika mentioned earlier. Also, many more intensity cards were returned during this period than previously.

The time duration studied is probably too short to consider the change in rate of strain release as

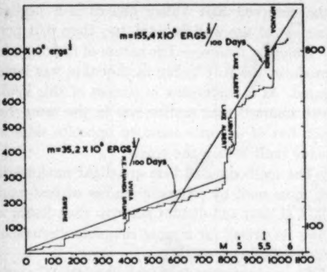

FIG. 5 – Strain release, Rift Valley earthquakes, from May 17, 1953 to April 1, 1956

an indication of a change in the regional rate of strain accumulation. It is possible that during the earlier period, the strain was not being released as efficiently and was accumulating in the crustal material at a greater rate than during the later period. Some downward curvature is noticeable on the plot during periods immediately following the larger shocks. This is caused by the influence of aftershock sequences of the larger shocks on the regional strain release. When plotted against a logarithmic time scale these portions approximate straight lines.

Figure 6 shows the rate of strain release from two Uvira aftershock sequences. The time scales are logarithmic. All of the observed shocks are included on these plots and, since our Uvira station was only a few kilometers from the epicenters, magnitudes down to about 0.5 are included. The shock of July 3, 1954, initiating the first series, was of magnitude 5.5 and had a maximum intensity of about VII near Uvira. The straight line shown has a slope of 35 × 10⁷ ergs½/log t(hours). On July 4 a shock of magnitude 4 near the original epicenter disrupted the strain release rate of the aftershock sequence. For this reason the plot was stopped at that time. On July 5 a shock of magnitude 4.5 at the same epicenter, within our location error, apparently started an independent aftershock sequence. The straight line shown here has a slope 16 × 10⁷ ergs½/log t(hours).

Figure 7 is a strain release graph for an aftershock sequence following two shocks of magnitudes approximately 4½ which occurred at a time interval of 13 minutes on August 3, 1955, about 20 km from Uvira. The slope shown here is 3 × 10⁶ ergs½/log t(hr).

Benioff has interpreted aftershock strain release proportional to the logarithm of the time after the initial shock, such as has been shown here, to be a result of the liberation of elastic creep strain stored in the surrounding rock before the initial shock, through the action of compressive or tensional stresses. Many of the shocks used here are considerably smaller than those based on previous studies of this kind. However, the results appear to be quite similar to those previously obtained.

The number of shocks recorded during the three-year period of observation, in each magnitude interval of 0.5 units, from magnitude 3 to 6.5, was counted. The results are shown in Table 1. The result of a plot of log N against M gives a fairly well determined straight line of slope −0.6. This logarithmic dependence has been found in aftershock sequences, regional earthquake studies, and global earthquake studies by other investigators. *Gutenberg* and *Richter* [1954] and *Gutenberg* [1956] in a more recent paper give a value of −0.9

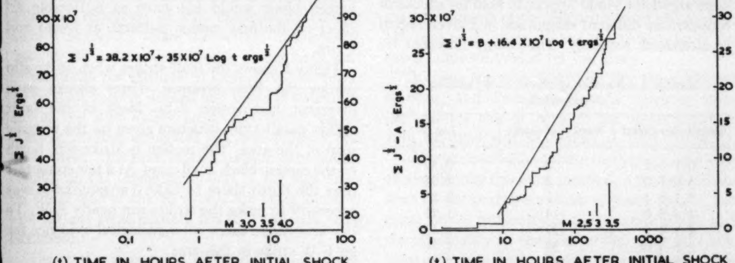

FIG. 6 – Strain release, Uvira aftershocks: starting July 3, 1954 (on left); starting July 5, 1954 (on right)

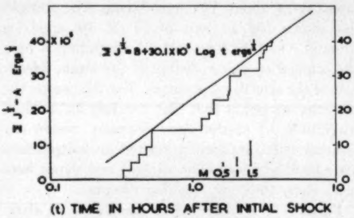

FIG. 7 – Strain release, Uvira aftershocks, starting August 3, 1955

with a small standard deviation for shallow shocks. One possible explanation for the low value found here is that the observation radius of the African stations decreases with decreasing magnitude and a larger area is monitored for the large shocks than for the smaller shocks. This same reasoning would apply on a world-wide scale for shocks below a magnitude of about 5.5 or 6, recording of which would be dependent upon location relative to the world's seismograph stations.

The total strain release over the three-year period from the Rift Valley shocks was about 8.5×10^{10} $\text{ergs}^{1/2}$, equivalent to an average rate of 2.8×10^{10} $\text{ergs}^{1/2}$/year. Benioff, using the same energy equation, has obtained a rate of about 80×10^{10} $\text{ergs}^{1/2}$/year for the strain release from all great earthquakes, magnitude 8 or greater, over a fifty-year period. Thus, the Rift Valley rate is about 3½ pct of that for the world's great earthquakes. This rate appears to be much too high. The 'constant' factor relating the square root of the energy to the strain contains a volume term which undoubtedly changes with magnitude, probably to a sufficient degree to make a direct comparison between the rates meaningless. The same argument would appear to hold for shocks of considerably different magnitude in a given region or aftershock sequence. The energy liberated by the observed Rift Valley quakes is a negligible portion of the world's total, less than 0.01 pct.

TABLE 1 – *Number of shocks as a function of magnitude*

Magnitude interval	Number of shocks	Log N
6.1–6.5	2	0.30

5.1–5.5	7	0.85
4.6–5.0	14	1.15
4.1–4.5	27	1.43
3.6–4.0	57	1.76
3.1–3.5	124	2.09

Nature of faulting—The nature of faulting which produces the Rift Valley earthquakes was investigated. As is customary in studies of this kind, it was assumed that motion was in the same direction but of opposite sense on opposite sides of a plane fault within the crust.

The methods used here are slight modifications of those used by others in studies of first-motion data at near and distant stations. (See *Sutton* and *Berg* [in press], for a more complete discussion of the methods.)

The near-station data from the IRSAC stations were interpreted using two different assumptions: (1) vertical faults with pure strike-slip motion; (2) near-vertical faults with pure dip-slip motion. In both cases fault strikes were drawn at the epicenter as near parallel the known faults in the area as possible, while keeping the first-motion data consistent with the assumed fault motion. The tectonic map of the Belgian Congo by *Cahen* [1952] was used for this purpose.

Under the dip-slip assumption a change in direction of first-motion would be expected when Pn becomes the first arrival [*Gutenberg*, 1941]. To account for this effect, circles were drawn around the stations at this critical distance and the first-motion within a circle was reversed for the station in question. To account for the first-motion at Astrida from a number of shocks under and near Lake Kivu, it was necessary to cut off the critical circle along a line roughly parallel to the structure in the area. This is approximately equivalent to assuming that the faults in the Lake Kivu area dip E S E at between 75° and 80° (assuming a focal depth of about 15 km). Because of the distribution of epicenters, and changes in fault strikes along the Rift Valley, a similar dip toward the graben block would not have as noticeable an effect on the first motion patterns at Lwiro and Uvira.

Figure 8 shows the fault strikes when strike-slip motion has been assumed. Three shocks gave divergent first-motion data. Most of the fault strikes parallel the structure given on the tectonic map of the area. The motion is strike-slip, north on the eastern block in all cases. At a few epicenters near the north shore of Lake Tanganyika it was necessary to make the strikes run nearly E-W. To our knowledge there is no geological evidence for an E-W strike in this area.

Figure 9 shows the fault strikes when dip-slip

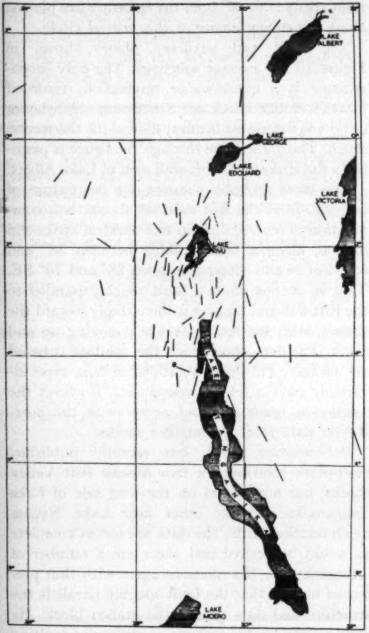

FIG. 8 – Fault strikes assuming strike-slip faulting, north on eastern side; each line represents one or more earthquakes; dashed lines indicate divergent data, solution obtained by disregarding data from one station.

motion is assumed. Here there were two cases where the data were divergent. The resultant motion pattern can be separated into five regions, with the exception of two earthquakes east of Lake Tanganyika where the motion was opposite that for the surrounding shocks. Going from west to east near the latitude of Lake Kivu, we have: up on west (poorly defined and possibly independent of the Rift Valley tectonic pattern); up on east; up on west, up on east (not well defined); and up on west. This fault motion pattern corresponds roughly to the topography; that is, the high areas on either side of the Rift walls are being elevated and the low areas between the Rift walls are being depressed.

The fault strikes south of Lake Kivu are somewhat distorted. However, the Kivu area is more complicated than portions of the Rift Valley to the north and south. The eastern Rift fault may be missing in this area and the graben block is at a higher elevation. There is a difference in elevation of about 700 m between the levels of Lake Tanganyika and Lake Kivu. Part of the apparent uniformity of the results for the more distant shocks may be a result of the insensitivity of the method for some of the more distant shocks because of the small angle subtended by the array.

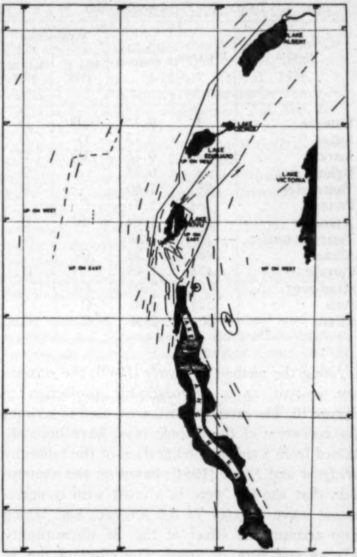

FIG. 9 – Fault strikes assuming dip-slip faulting; each line represents one or more earthquakes; dashed lines indicate divergent data, one station omitted from solution.

Thirteen stations, including the three IRSAC stations, and Entebbe, Uganda, reported first-motions for one or both of the earthquakes of July 22, 1956 and September 4, 1956 (Table 2).

As mentioned before, these earthquakes occurred at very nearly the same location, a few kilometers west of the northwest shore of Lake Albert. Because of the proximity of the two epicenters, and the consistency of the first-motion data from stations reporting both shocks, the two shocks have been treated as one.

TABLE 2 – *First-motion data*

Station	Distance	Extended distance	First-motion	
			Sep. 4, 1955	July 22, 1955
	°			
Entebbe	3	0.75	cD	D
Lwiro	4½	0.75	D	D
Astrida	4½	0.75	D	D
Uvira	5	0.75	...	D
Tananarive	28	1.60	...	D
Pretoria	28½	1.61	C	...
Jerusalem	30	1.64	dC	D
Tammenrasset	32	1.69	...	C
Alicante	46	1.92	C?	...
Cartuja	47½	1.95	...	C
Strasbourg	50½	2.02	D?	...
Paris	52½	2.07	C	...
Kiruna	66	2.49	C	C

Using the method of *Byerly* [1942], the stations are plotted on a stereographic projection in Figure 10. The extended distances, used to account for curvature of the seismic rays, have been obtained from a simple modification of the tables by *Hodgson* and *Storey* [1954]; based on the assumption that the foci were in a crust with compressional wave velocity of 6.5 km/sec, and taking into account the effect of the *M* discontinuity (*Sutton* and *Berg*, in press]. The effect of the *M* discontinuity on the extended distances for stations at distances between that for which *Pn* becomes the first arrival and about 10° is to create a critical circle around the epicenter whose radius is a function of the critical angle for *Pn*. Stations from about 1° to 10° from the epicenter are plotted along the circumference of this critical circle.

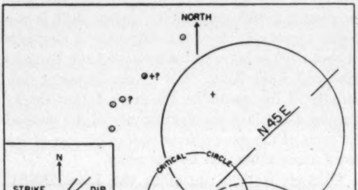

FIG. 10 – First-motion, shocks of July 22 and September 4, 1955, 1° ¾ N, 30° ½ E

The fault and auxiliary planes shown in Figure 10 are average solutions. The only inconsistency is a questionable rarefaction, recorded for the earlier shock at Strasbourg. Strasbourg could not determine the first motion for the second shock. The dashed line through the figure is parallel to the strike of the rift wall west of Lake Albert.

The most probable solution for the nature of faulting, from the first motions shown, is a combination of reverse dip-slip and sinistral strike-slip motion, along a fault striking between 38° and 66° E of N and dipping between 58° and 70° SE. That is, motion along a fault roughly parallel to the Rift wall and dipping rather steeply toward the graben, with the southeast block moving up and north. The data upon which this solution is based are meager. Published solutions of this type invariably have a few inconsistencies. However the solution is reasonable and agrees with the near-station data from the smaller shocks.

DeBremaecker [1956] has recently published fault-plane solutions for two African Rift Valley shocks, one near Uvira on the west side of Lake Tanganyika and the other near Lake Nyassa much further south. The data are not as complete as would be desired and there are a number of inconsistencies. His solutions agree with that presented here in that the fault roughly parallels the structure and dips toward the graben block. He finds a considerable amount of strike-slip faulting combined with normal dip-slip in one case and reverse dip-slip in the other.

Conclusion—The data presented here give some information about the tectonic activity in the interesting Rift Valley region of Africa. They indicate that the present earthquake activity is located along faults which in most cases are parallel to the Rift walls. Isointensity lines are elongated in these same directions. Limited data indicate fault dips toward the graben block. The average direction of faulting could be strike-slip, north on the eastern side or dip-slip with the upwarped marginal ridges being further uplifted and the graben block further lowered, or some combination of the two. If the logarithmic rate of aftershock strain release is indicative of tensional or compressional elastic creep strain this would presumably favor the dip-slip interpretation.

The rate of strain release increased by a factor of 5 about July 1956. This change was coincident with the commencement of activity west of Lake

Albert and east of Lake Tanganyika. A longer observation period is probably necessary to determine whether or not this represents a change in the regional rate of strain accumulation.

Acknowledgments—The research reported here was made possible by a William Bayard Cutting Traveling Fellowship from Columbia University and a Belgian-American Educational Foundation Fellowship which enabled the first author to exchange positions with J. Cl. DeBremaecker as seismologist at IRSAC for one year. The cooperation of the East African Meteorological Service and the seismologists who kindly supplied data used in this study is gratefully acknowledged.

Short-Period Oceanic Surface Waves of the Rayleigh and First Shear Modes*

JACK OLIVER AND MAURICE EWING

Abstract—Waves corresponding to the short-period segment of the Rayleigh mode and to the first shear mode are identified for paths traversing the deep ocean, apparently for the first time. It appears that the reason for the presence of the waves in this case and their conspicuous absence in all other cases is that (a) the shock which excited these waves is the atomic explosion of Operation Wigwam, deep in the Pacific Ocean; (b) earthquake sources are generally too deep to excite short-period surface waves efficiently. The new data strongly support the normal mode explanation for the dispersion of Rayleigh waves crossing the Pacific Ocean and furnish supporting evidence for the crustal structures previously deduced from surface wave dispersion and from refraction shooting. The unusual characteristics of the body phases and the *T* phase may probably be explained, as well, by assuming the source was within the water layer.

Introduction—A group of seismograms of unusual appearance was recorded at Palisades from the shock of May 14, 1955 in the Pacific Ocean off Lower California. The U. S. Coast and Geodetic Survey placed the epicenter at 29°N, 126½°W, the time at 20h 00m 00s GMT. Although no magnitude has been reported, the Bulletin of the Bureau Central International de Seismologie (Strasbourg) gives arrival times for *P*, *S*, and other body phases for 54 stations from every continent except Antarctica. Upon inspection, records from several west coast and Hawaiian seismographs also revealed unusual characteristics, some similar to those at Palisades. Three striking effects were noted: (1) a prolonged oscillatory and very nearly sinusoidal character in the body waves, *P*, *PP*, and *S*; (2) a surface wave train of the Rayleigh type of surprisingly long duration and including waves of short period in an unusual dispersive pattern; a *T* phase of extremely large amplitudes at the west coast and Hawaiian stations.

A more detailed investigation revealed that the major parts of the surface wave trains could be explained satisfactorily as the result of normal mode propagation in the oceanic and continental structures along the path. For the oceanic segment, however, it was found that modes and portions of modes of propagation had been excited which had never before been observed from an earthquake source. In fact, the excitation was such that an extremely shallow source, possibly within the water layer, seemed likely. Since a source so located could also account for the other observed features, it seems almost certain that this particular shock is the deep atomic explosion of Operation Wigwam which was reported to have been detonated in the area sometime during May 1955. That the epicenter is not in a seismic belt and that the time of occurrence falls on an even hour (12 noon PST) support this view very nicely.

Regardless of the nature of the source, this shock is a very important one to the study of surface wave propagation over oceanic paths since it excited two types of surface waves which had not previously been found to propagate along oceanic paths. One type corresponds to the short-period branch of the Rayleigh wave curve computed from a crustal model deduced from seismic refraction results and from the analysis of the long-period Rayleigh waves. The second type corresponds to the next higher mode, here called the first shear mode. These observations prove that the absence of short-period Rayleigh waves on earthquake seismograms for oceanic paths does not require a major revision of the present structural model.

Once the dispersion for the oceanic portion of the path is understood, the explanation for the Palisades surface wave train follows readily. The train consists primarily of waves crossing both the oceanic and continental portions of the path in the fundamental Rayleigh mode. The slow velocity of some of the waves is the result of propagation near the group velocity minimum in both cases.

EXPERIMENTAL DATA

Surface waves—Figure 1 shows the surface wave portion of the Palisades seismogram of this shock. Instrumental constants and the time correction are also shown. The record contrasts greatly with Palisades seismograms of west coast shocks in that (a) the duration of the directly arriving surface wave train is much greater than usual and (b)

---

* Lamont Geological Observatory Contribution No. 290.

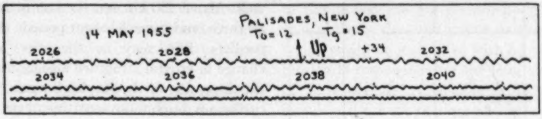

FIG. 1 – Palisades seismogram, surface waves

short period, large amplitude waves of the Lg type are absent. Since this shock is farther offshore than most shocks in the vicinity of the west coast, records from the Berkeley, Fresno, and Pasadena stations were examined in an effort to isolate the effect of the oceanic portion of the path. Surface wave dispersion at these stations is plotted in Figure 2. Standard surface wave analysis techniques have been used [*Ewing* and others, 1957]. When the wave trains are irregular the period has been obtained by measuring over a few cycles of a group. The Berkeley and Pasadena data obtained in this manner are in good agreement.

Also shown in Figure 2 are theoretical curves of group velocity versus period for the Rayleigh and first shear modes for a crustal structure typical of the deep oceans. The structural model used is also shown in Figure 2, where α is the compressional wave velocity, σ is Poisson's ratio, and H is the thickness of the upper and the intermediate layers. The fit of the data to the curves is generally very good and is the chief basis for the wave identification. Waves corresponding to the segment of the Rayleigh mode in which the periods decrease with decreasing velocity are present, as is normally the case with earthquake sources. In addition, however, waves corresponding to the group velocity minimum and to the short-period segment of the curve in which periods increase with decreasing velocity are present. Furthermore, some waves which clearly correspond to the first shear mode are also present. Waves corresponding to this mode and to the short period segment of the Rayleigh mode, with the exception of the T phase, have never been identified in the case of earthquake sources.

It has been suggested that the reason for the absence of these waves is the depth of the source. Theoretical calculations [*Press* and others, 1950] have shown, as one might determine intuitively, that as the depth of the source beneath the ocean bottom is increased, the relative excitation of the shorter waves diminishes much more rapidly than that of the longer waves. With this hypothesis, however, it is necessary to rely on topographic effects near the source to account for the excitation of the T phase by earthquakes. Alternative proposals are that waves in the short-period range suffer great attenuation, possibly by absorption or by scattering, when traversing oceanic paths, or that some presently unknown but wide-spread crustal feature affects propagation of waves in this period range strongly.

The present data indicate that, for the path under study, attenuation is not of major importance to dispersion studies and that variations from the assumed crustal structure are small. The fact that the short-period waves are strongly excited implies a very shallow source, and the data appear to be in agreement with a source in the water layer. This deduction is based on comparison with theoretical calculations and experimental data from countless earthquakes.

The experimental data of Figure 2 establish the thickness of the liquid layer of the theoretical structures at about 4.5–4.6 km. Since this layer is meant to include both the water and unconsolidated sediments the average thickness of the sediments can be found by subtracting the mean water depth along the path from the liquid-layer thickness [*Ewing* and others, 1957]. This gives a value between 0 and ¼ km for the sediment thickness. A refraction profile by *Raitt* [1956; M_1 in his notation] at one point in the area gave 0.26 km for sediment thickness, in good agreement.

At the long-period end of the spectrum, points corresponding to the Rayleigh mode are slightly low. This might be expected if the crustal structure is slightly modified from that typical of the deep

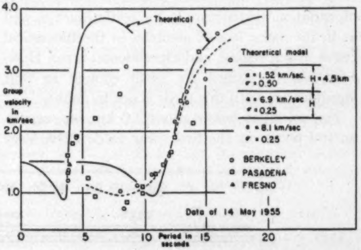

FIG. 2 – Surface wave dispersion over oceanic portion of path

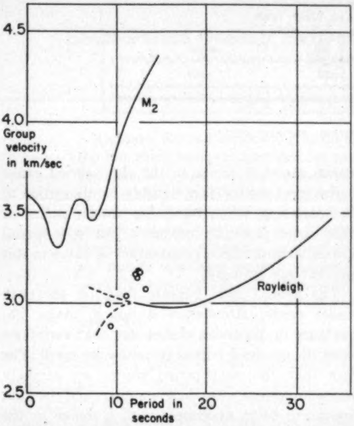

FIG. 3 – Surface wave dispersion over continental portion of path

ocean as the mean water depth, smaller than average for the oceans, would suggest. Raitt's profile lends support to this idea. It is encouraging that the velocity tends to be slightly slower, if anything, to Berkeley than to Pasadena, indicating a little more departure from the typical oceanic crust. This is just what would be expected from the bottom topography of the area, the depth along the path to Berkeley being, on the average, slightly less. No corrections have been made for the continental portion of the path, however, and there is always the possibility of an error in epicenter location, so this point is somewhat speculative.

Near and to the left of the minimum, points corresponding to the Rayleigh mode also deviate slightly from the theoretical curve. This may be the result of many influencing factors including effects of variation in structure in the water layer as well as in the rocks, loss of precision in the theoretical curve in this region, and experimental error. However, the deviations are small enough so that identification with this mode is not in doubt.

For velocities below about 2.0 km/sec, experimental points fit the first shear mode curve very well. Above 2.0 km/sec the points are sparse, but all three tend toward longer periods than the curve predicts. This may be the effect of the small change in crustal structure also required to satisfy the dispersion of the Rayleigh mode. Higher mode curves are much more sensitive to small changes in structure. Extensive calculations which the data do not warrant would be required to make certain of this. It does appear certain, however, that waves corresponding to at least a portion of the first shear mode have propagated along the oceanic portions of the paths between the epicenter and Pasadena and Berkeley. Propagation in this mode had been suggested previously but no certain identification had ever been made of these waves or of the short-period waves of the Rayleigh mode in the deep ocean prior to the present study. Waves of a similar nature, however, are frequently found in shallow water studies where the source is an artificial one located in the water layer.

The dashed line of Figure 2 is the experimentally determined dispersion curve for waves in the Rayleigh mode. Using this curve to obtain the travel times over the oceanic portion of the path, the dispersion curve for waves crossing the continental portion can then be easily deduced from the Palisades data. The results are shown in Figure 3. The waves appear to have crossed the continent in the Rayleigh mode rather than one of the higher modes, and the periods recorded correspond largely to the broad flat portion of the Rayleigh mode curve of earthquake-generated continental surface waves. The curves shown for the Rayleigh and M_2 modes are experimental ones found in earlier studies [*Oliver* and *Ewing*, 1958]. Thus most of the dispersion at Palisades is due to the oceanic rather than the continental segment of the path. Although there is some uncertainty in the points of Figure 3 because the exact length of the ocean path is somewhat in doubt, it is not possible to vary this length enough to affect the identification. The length of the oceanic segment used for the points shown was 800 km. It is interesting that there appears to be a slight 'tailing off', that is, slowing, at periods of about ten seconds. This phenomenon has frequently been noticed in studies of earthquake waves from west-coast shocks. It is not yet completely understood but may be the effect of the

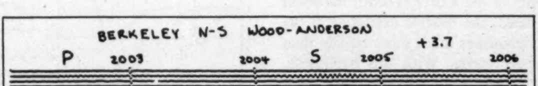

FIG. 4 – Berkeley seismogram, body waves

surficial sedimentary layers on the Rayleigh wave propagation. It is clear from the measured velocity, however, that the waves have crossed the continent in the Rayleigh mode.

T Phase—Exceptionally large *T* phases were recorded by the California station and according to newspaper reports, felt along the California coast. At Hawaii, virtually the entire seismic effect was a *T* phase of large amplitude. A notation on the seismogram indicates that it was felt on northeast Oahu and hence misinterpreted originally as a local earthquake.

T phases may be thought of as waves of very short period (<1 sec) propagating as one or more of the normal modes, although these modes, as shown in Figure 2, might be modified very slightly in this period range by the velocity structure of the water and sediments.

In addition to the wave guide effect due to the gross crustal structure, *T* phase propagation is aided greatly by the sound channel within the water, that is, the sofar channel [*Ewing* and others, 1957]. Earthquakes frequently excite *T* phases in spite of their depth beneath the surface, an effect usually attributed to topographic irregularities. However, the relative amplitudes in the present study are so large that a source within the water layer, possibly very near to the axis of the sofar channel is strongly suggested.

That Operation Wigwam excited strong *T* phases is evident from the study based on these waves by *Sheehy* and *Halley* [1957]. They studied the attenuation of sound in water using reflected *T* phases and found arrivals with travel times up to nearly four hours. They did not, however, publish the date, time, and exact location of the test. They do give the arrival times, but not the date, of *T* phases at west coast and Hawaiian stations. These times are in excellent agreement with the origin time of 20h 00m 00s GMT and the location given by the U.S.C.&G.S. Sheehy and Halley also state that the test shot of Operation Wigwam was fired in the deep sound channel.

Body phases—The body phases *P*, *PP*, and *S* show a pronounced oscillatory character of long duration wherever recorded (Fig. 4). The *S* phases consist almost entirely of waves having periods of about 2.4 sec. This period is most prominent in the *P* and *PP* phases but these also include waves of about a 1.3-sec period. Records from the short-period seismographs show periods of about 0.75 sec and possibly some that are even shorter, but the unusual long oscillatory character is due primarily to the 2.4- and 1.3-sec waves. Since waves of this period are not prominent in the *T* phase, it is unlikely that the source or the bubble pulse which would be associated with an underwater explosion is responsible for the long trains of waves of these periods. A possible explanation may be found in the work of *Burg* and others, [1951] who found waves of prolonged sinusoidal character in seismic prospecting records taken in a water-covered area. Essentially, they attribute these 'tones' to standing waves in the water layer which leak gradually into the substratum. Using the liquid-layer depth found in the section on surface waves, it can easily be determined that periods of 2.4 and 1.3 sec correspond almost exactly to the third and fifth normal modes. Why these modes should be excited and not the others probably depends on condition at the source, possibly on the spectrum at the source when the bubble pulses are included. In favor of this hypothesis is a slight decrease in period in the long *S* wave train at Berkeley, as predicted by the analysis of *Burg* and others. It is apparent that body-wave data do not conflict with the placement of the source within the water layer. A more thorough study of this portion of the seismograms would require information on the source and location which is not generally available.

Acknowledgments—The authors express their appreciation for the loan of the seismograms from the Berkeley, Fresno, Honolulu, and Pasadena stations. The work reported in this paper was supported by Contract AF 19(604) 1369 between the Air Force Cambridge Research Center and Columbia University, and Grant NSF-63485 from the National Science Foundation.

Velocity of Seismic Waves in the Earth's Mantle*

B. GUTENBERG

Abstract—On the basis of our present knowledge the Earth's mantle may be divided into four sections: (a) from the Mohorovicic discontinuity to a depth of about 200 km, with small changes in the wave velocities which have minima in this section; (b) from 200 to 950± km with relatively rapid, fairly regular increase in velocity; (c) from 950 to 2700± km with smaller and less regular increase in velocity; almost straight line portions of the travel-time curves and relatively small wave amplitudes at certain ranges of distance indicate at least two portions of (c) where the wave velocity increases relatively little with depth; (d) from 2700 km depth to the core boundary with little change in velocity and probably maxima roughly 100 km above the core boundary.

Bullen [1953, p. 209] has divided the Earth's interior into regions of which B, C, and D constitute the Earth's mantle. New data on travel times and amplitudes as function of the epicentral distance have made it advisable to attempt a revision of this division. It is now believed widely that the velocities of P and of S do not change much and partly decrease in the upper 200 ± km of the mantle, and probably reach minima at depths between 100 and 200 km. On the other hand, no evidence seems to exist any longer for a first or second order discontinuity at a depth near 400 km. This discontinuity had been found on the assumption that the velocities increase everywhere in the upper mantle, and effects of the layer with relativity low velocity near the top of the mantle had been attributed to the nonexisting discontinuity at 400 ± km depth.

To find the velocity in the mantle as a function of depth, effects of all irregularities above 200 km must be eliminated by calculation, and the usual procedure to obtain velocities must be applied to this hypothetical Earth. The velocities v_s of P and S as function of the depth r_s can then be based on Wiechert's equation [*Wiechert* and *Geiger*, 1910]

$$\log r_s = 3.80393 - 0.0024127 \int_0^{\Theta_s} q \, d\Theta \qquad (1)$$

where cosh q is the ratio of the apparent velocity $\bar{v}_s$ at the angular distance Θ_s to all corresponding values of $\bar{v}$ between $\Theta = 0$ and $\Theta = \Theta_s$. The velocity v_s at the distance r_s from the Earth's center is given by

$$v_s = r_s \bar{v}_s / r_0 \qquad (2)$$

r_0 = Earth's radius. If $\bar{v}$ changes rapidly with distance, the velocity increases rather rapidly with depth at the depth r_s where the ray emerging at Θ_s has its deepest point; if the travel time curve is nearly straight near Θ_s, the change in velocity at the corresponding depth r_s is relatively small.

Another way to find information on changes of velocity with the depth r_s is based on the change in amplitudes of a given phase with the distance Θ_s. The amplitude a (in microns) of a body wave (period T) arriving at the distance Δ in a shock of magnitude m may be expressed to a first approximation [*Gutenberg*, 1945] by

$$\log(a/T) = m - A \qquad (3)$$

where m is the unified magnitude of the shock [*Gutenberg* and *Richter*, 1956]. For shallow shocks

$$A = 6.3 - \log B - \tfrac{1}{2}[\log C + 0.43\, kD + \log \tan i_0 + \log |di/d\Theta| - \log \sin\Theta] \qquad (4)$$

The value 6.3 is an empirical constant which depends on the definition of m and is practically equal for P- and S-waves [*Gutenberg*, 1945, p. 61]; B is the ratio of the ground amplitude in the observed wave to the incident amplitude; B depends only on the wave type and the angle of incidence i_0 at the surface; Θ is the angular epicentral distance; C is the product of the ratios of the amplitude of the reflected or refracted wave to that of the incident wave at discontinuities; for values of B and C, see *Gutenberg* [1944]; for P and S it may be assumed that $C = 1$, neglecting the effects of discontinuities in the crust and of the Mohorovicic discontinuity. D is the distance along the ray; for P, PP, and S within the limits of errors kD may be replaced by $k\Delta$; k is the coefficient of absorption for the energy; $k = 0.12$ per 1000 km [*Gutenberg*, 1945, p. 58]. It does not depend noticeably on the periods of P and S for $\Delta > 2000$ km [*Gutenberg*, in press].

---

* Contribution No. 853, Division of the Geological Sciences, California Institute of Technology, Pasadena, California.

The angle of incidence i_0 at the distance Δ (in km) is given by

$$\sin i_0 = v_0/\bar{v}_\Delta \qquad \bar{v}_\Delta = d\Delta/dt \qquad (5)$$

The selection of v_0, the velocity at the surface of the Earth, depends on the period of the waves since the wave lengths vary from a fraction to a multiple of the crustal thickness; for P, values of 6.1 as well as of 8.2 km/sec have been used, and for S values of 3.5 and 4.7 km/sec. The resulting calculated values of *A* are smaller by about 0.2 near $\Theta = 30°$ and by about 0.1 near 90° for the

TABLE 1 – *Values of log a/T calculated from (3) to (5) for v_0 = 6.1 km/sec for P and v_0 = 3.5 km/sec for S for a shock of magnitude m = 6; a = amplitude in microns, T = period in sec, i_0 = angle of incidence at the surface, θ = angular epicentral distance*

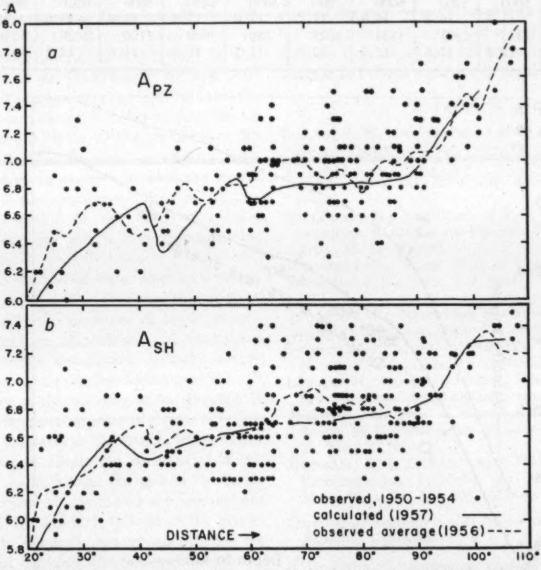

FIG. 1 – Values of *A* (a) for vertical component of *P*; (b) for horizontal component of *S*; observed values are calculated from (3) by using amplitudes *a* and periods *T* reported by 18 stations for shallow earthquakes of magnitudes *m*; calculated curves are based on travel time curves (4); the curves "Observed averages (1956)" are based on *Gutenberg* and *Richter*. [1956, Table 2]

vertical component of P, if $v_0 = 6.1$ km/sec instead of 8.2 km/sec. For S waves, an additional uncertainty arises from the fact that B depends on the direction of polarization. Fortunately, for angles of incidence between 0° and about 35°, log $B = 0.3$ within the limits of error regardless of the direction of polarization. If the velocity $v_0 =$ 3.5 km/sec, this is fulfilled for $\Theta > 22°$, that is, for all distances considered here; if $v_0 = 4.7$ km/sec, this is fulfilled only for distances over 50°. For small epicentral distances log B may vary appreciably with distance.

Table 1 contains selected calculated values for a/T on the assumption of travel times for a surface focus, for P by *Gutenberg* [1953], and for S by *Jeffreys* and *Bullen* [1948]. Corresponding calculated curves for A have been entered in Figure 1 and in similar other figures not reproduced including one for PP. They agree within the limits of error with the observations. It follows that the constant 6.3 in (4) is correct within about 0.2 units for P, PP, and S, and that consequently in earthquakes the same amount of energy, within a factor between $\frac{2}{3}$ and $1\frac{1}{2}$, enters into the longitudinal and the transverse waves.

Since there is no noticeable systematic divergence with increasing distance between the theoretical curves, all based on the same value of k, and the observed amplitudes it follows that k is roughly the same for P and S.

The amplitudes (Fig. 1) can be used to find depth ranges in the Earth where the velocity

TABLE 2 – *Apparent velocities $\bar{v}$ in km/sec, (a) calculated by Wiechert and Geiger [1910] from travel times at the distances Δ, corresponding depths d of the deepest points of the ray and corresponding velocities v_a for P; (b) values on the basis of travel times of Gutenberg [1953]*

changes with depth faster or more slowly than average. If the travel-time curve is nearly straight, and the velocity does not increase much with depth, $|di/d\Theta|$ is small (Eq. 5), A in (4) is relatively large, and the amplitudes a are relatively small (3). Thus, relatively small amplitudes correspond to small increase (or even decrease) of velocity with depth at the deepest point of the ray. Similarly, large amplitudes indicate relatively large increase in velocity at the depth r_s. The investigation of changes in velocity with depth on the basis of observed amplitudes as function of epicentral distance [*Zoeppritz*, *Geiger*, and *Gutenberg*, 1912] is based on this fact.

Wiechert and *Geiger* [1910] made the first calculation of the velocity as a function of depth by use of (1) which they applied to travel time curves of Wiechert-Zoeppritz. Corresponding to their almost straight-line travel time curve section beginning at about $\Delta = 5400$ km ($\bar{v}$ almost constant, Table 2a) they found practically constant wave velocity downward from a depth of about 1500 km which Wiechert considered as the boundary of the core. However, it corresponds to the relatively straight line portions of the travel time curve which we find now (for example, *Gutenberg* [1953]) at distances from about 40° (4440 km) to 44° and from about 53° to 63° (compare (a) and (b) in Table 2). Newly calculated wave velocities as function of depth are shown in Figure 2. The beginning of the portion with smaller increase in velocity with depth was moved to a depth of 1200 km in the first attempt to use amplitudes in the determination of the structure of the Earth [*Zoeppritz*, *Geiger*, and *Gutenberg*, 1912]. It corresponds now to $d = 950$ km.

The original method of using amplitude ratios, especially PP:P, has the advantage that it gives relatively sharply the distances of nearly discontinuous changes in amplitudes, but errors are introduced by the assumption that the energy starting at the source in the direction of the PP ray is the same as that starting in the direction of P; moreover, the varying ratio of the wave length of PP to the thickness of the crustal layers at the point of reflection affects the constant C in (4). On the other hand, abrupt changes in curves for the average observed amplitudes are unintentionally replaced by gradual transitions in graphs like Figure 1. Similarly, travel-time curves are smoothed, and therefore the corresponding derivatives $d\Delta/dt$ can not show second-order discontinuities. Nevertheless, there is fair agreement now between ranges of distances, where the curvature of the travel time curve is small, and those where relatively small amplitudes are observed (compare Fig. 1).

Relatively regular changes in the slope of the travel-time curve and in the observed amplitudes at epicentral distances of less than 40° indicate that the relatively large increase of wave velocities between depths of about 250 and 900 km is fairly regular. However, in the deeper portion of the mantle, there are at least two sections, one between depths of 900 and 1000 km, another between 1400 and 1500 km (Fig. 2) where the velocity increases relatively slowly with depth (see $\bar{v}$ in Table 2 (b) and *Gutenberg* [1953, Table 2]).

The conclusion that both velocities decrease immediately above the core, is based on practically straight travel-time curves approaching the end of the curves for the direct P and S as well as by relatively small wave amplitudes at the corresponding epicentral distances near 100°. The distance of $\Theta = 103°$ where the P waves arrive which touch the core at their deepest point is marked by a rapid decrease in amplitudes with distance. For S waves, this point is reached at a slightly greater distance than for P; the difference results from an increase in Poisson's ratio with depth.

EXTRAPOLATION OF SCALAR MAGNETIC INTENSITY ALONG A RADIUS FROM THE CENTER OF THE EARTH

An approximate method of extrapolating the scalar magnetic intensity along a radius from the center of the Earth is obtainable through a development similar to that applied in the extrapolation of geomagnetic field components [*Zmuda*, 1957a].

In regions that are outside sources of magnetism, the components of the geomagnetic intensity may be expanded in a series of solid spherical harmonics. In polar coordinates r, θ, and ϕ, with origin at the Earth's center, the respective series are

$$X = \sum_{n=1}^{\infty} \sum_{m=0}^{n} \left(\frac{a}{r}\right)^{n+2} \frac{\partial}{\partial\theta} f_n^m(\theta, \phi) \qquad (1)$$

$$Y = -\sum_{n=1}^{\infty} \sum_{m=0}^{n} \left(\frac{a}{r}\right)^{n+2} \frac{1}{\sin\theta} \frac{\partial}{\partial\phi} f_n^m(\theta, \phi) \qquad (2)$$

$$Z = -\sum_{n=1}^{\infty} \sum_{m=0}^{n} (n+1) \left(\frac{a}{r}\right)^{n+2} f_n^m(\theta, \phi) \qquad (3)$$

where X, Y, and Z, are respectively the northern, eastern, and downward components; a is the radius of the Earth; and f_n^m is a spherical surface harmonic of degree n and order m.

In terms of the field components, the scalar magnetic intensity F may be written as

$$F^2 = X^2 + Y^2 + Z^2 \qquad (4)$$

Squaring each series in (1), (2), and (3), and then substituting in (4), one obtains for the intensity at collinear points

$$F^2 = \sum_{c=0}^{\infty} F_c^2 \left(\frac{a}{r}\right)^c \qquad (5)$$

or

$$F^2 = \sum_{c=0}^{\infty} F_c^2 e^{-2\tau_c h} \qquad (6)$$

where F_c is part of the total intensity observed at $r = a$; e is the base of the natural logarithm; τ_c equals $c/2a$; h is the distance above the surface $r = a$. The variation with altitude in (6) is obtained from that in (5) with the aid of the following relationships

$$\begin{aligned} \left(\frac{a}{r}\right)^c &= \left(\frac{a}{a+h}\right)^c \\ &= \left[\left(1 + \frac{h}{a}\right)^{a/h}\right]^{-ch/a} \\ &\cong e^{-ch/a} \end{aligned} \qquad (7)$$

Under the assumption that the variation with altitude in (6) may be adequately characterized by the use of a single τ, (6) may be written as

$$F^2 = F_0^2 e^{-2\tau h} \qquad (8)$$

or

$$F(h) = F_0 e^{-\tau h} \qquad (9)$$

where F_0 is the total value of F at a point on the surface $h = 0$.

Eq. (9) is similar in form to the expressions applicable to the extrapolation of field components.

With (9), if F is known at two points along a radius, τ may be obtained and then used to compute F at additional, collinear points. When the measurements are made at points that do not lie along a radius from the Earth's center, the exponential formula of (9) is not applicable; but the extrapolation may be effected by means of a Taylor series [*Zmuda*, 1957b].

Studies wherein it may be profitable to use either the exponential formula of (9) or the Taylor series are, for example, analyses of satellite magnetic data or of the total magnetic anomalies treated in geophysical prospecting.

Acknowledgment—This work was supported by the Bureau of Ordnance of the Department of the Navy under contract NOrd 7386.

PARLIAMENT OF SCIENCE, MARCH 15–17, 1958

Under the auspices of the American Association for the Advancement of Science, a Parliament of Science was held in Washington on March 15–17, 1958. The purpose of the conference was to discuss problems of science and public policy affecting the support of science and the improvement of science education. Some 130 participants and approximately 100 observers conferred at the Sheraton-Park Hotel, on the following five major topics: (1) The support of science; (2) The organization and administration of the Nation's scientific effort; (3) Communication among scientists and communication of scientific information; (4) The selection, guidance, and assistance of students for scientific careers; and (5) The betterment of teaching and education generally, as well as in the sciences.

The conferees agreed on several principles: (1) Scientific endeavor is one phase of human intellectual effort, and in order to flourish must be correlated with humanistic efforts; (2) In order to be wisely applied to human welfare, scientists must be free to communicate with each other and with the public; and (3) Scientists are concerned with the finding of new truth, and as citizens they have responsibility to indicate the social consequences of their scientific findings.

As a corollary of these principles, it seemed to be the majority view that we are tending to over emphasize the need for people educated in the physical sciences, mathematics, and engineering. Although men of these kinds are needed, it is also necessary to train more natural and social scientists, and to teach all scientists to be better citizens.

As to the organization of science, the coordinating function of the National Science Foundation was strongly recognized and endorsed. It was judged unnecessary, however, for a separate Department of Science to be set up in the federal government. It was also considered undesirable to have a separate "West Point of Science," in which scientists would be trained under federal auspices.

The following statement is quoted from the Conclusion of the draft report of the Parliament:

"Although this Parliament of Science has quite properly concentrated on problems of science and public policy, and although some of the recommendations are quite specific to science, it must be emphasized in conclusion, as it was in beginning, that science represents only one part of intellectual endeavor. Both public policy and the welfare of science require an educational system that is strong at all levels and in all fields of knowledge. Efforts to advance science at the expense of other fields of learning would harm all fields of learning and the society they serve."

The advent of the International Geophysical Year and its program of Earth studies is serving to advance a major portion of the program this Committee has been sponsoring over the past twenty years. Many of the members of the Committee are closely identified with the program for the International Geophysical Year, and this overlapping of interests is bound to be reflected in the Committee's activities. The present report will deal principally with studies that have been undertaken by the Committee and its members for a number of years and with activities that are not identified with the IGY effort.

Seismological studies—Among the many important studies now in progress under IGY sponsorship which are a continuation of earlier studies are the seismological studies of crustal structure based on surface explosive blasts. In this field, attention is called to the work of two groups who are working in plateau areas to test the universality of the apparently anomalous results obtained earlier in such regions. In the Andean Plateau of South America the Department of Terrestrial Magnetism of the Carnegie Institution of Washington has been making measurements near Cerro de Pasco, and in the central plateau of Mexico the University of Wisconsin has been making measurements near Durango. Earlier crustal measurements based on explosive blasts carried out in both the Colorado Plateau and the Plateau area of South Africa indicated that the thickness of the crust as defined by the 8 km/sec discontinuity is of the order of 30–35 km.

This is essentially the same value that is found to be characteristic of the continental coastal areas. In view of the well established verification of the hypothesis that crustal thickness and surface elevation are directly related in a manner analogous to that embodied in the Airy theory of isostasy in crossing on to the continents from the ocean basins, the plateau areas of high elevation would be expected to be underlain by a crust approaching 50 km in thickness. That the seismic studies in the plateaus did not confirm this was a distinct surprise, particularly since both of the plateaus studied are characterized by marked regional negative Bouguer gravity anomalies approximating −175 mgal. Verification of the original measurements in the Colorado Plateau area by studies conducted by the University of Utah based on the large blasts fired near Salt Lake City this past year would tend to rule out possible faulty observations as an explanation, as would the very extensive and detailed measurements that were made in South Africa.

Analyses made at the University of Wisconsin of crustal-structure variations based on gravity data, while showing excellent agreement with the results from seismic blast studies as regards the transition in structure in crossing from oceans to the continents, suggest a crustal thickness from 12 to 15 km greater than is indicated by the blast data in continental areas of high elevation. A clue as to the cause of this discrepancy is offered by the recent phase-velocity-dispersion studies of surface waves from distant earthquakes carried out by the Lamont Geological Observatory of Columbia University and the Seismological Laboratory of the California Institute of Technology at Pasadena. These surface-wave studies suggest variations in crustal thickness on the continent that are in substantial agreement with the results based on the analysis of gravity data. This implies that the cause of the discrepancy lies in the surface-blast measurements and that the explanation is probably related to variations in velocity structure within the crustal layer itself that are not being detected by the measurement techniques now being employed.

Seismic results of interest that are being obtained in connection with the IGY glaciological program relate to the thickness of ice in Antarctica. In Marie Byrd Land, a thickness of ice of about 10,000 ft has been found, placing the rock surface at the base of the ice about 5000 ft below sea level. A similar thickness of ice is reported for the South Pole and at several other locations.

While full reports are not available as to the success achieved in recording the subsurface atomic blast fired by the AEC in October, it appears that the blast was recorded with field equipment out to the 20-degree discontinuity in Mexico by the University of Wisconsin team working on crustal structure in that area, and at closer distances in Nevada, Utah, and California by various other groups. It is earnestly to be hoped that the policy of notifying the scientific community in advance as to blast times, and that of releasing information as to the instant of the explosion, will be continued.

Another portion of the IGY program that is of interest is the expanded network of continuous recording seismograph stations established throughout the world. These can be expected to yield much data that will help clarify the present picture of crustal structure beneath the continents and ocean basins as well as the deeper structure within the earth.

From a tectonic standpoint, it is of considerable interest that recent careful analyses of earthquake data show that the predominant movement associated with recent earthquakes has been one involving transverse motion rather than vertical displacement.

Gravity—One of the principal objectives of the U. S. IGY program is the establishment of an international worldwide set of gravity control points that can be used both for integrating the world's gravity data into a unified whole and as a standard for the calibration of relative gravity measuring devices. This work is a continuation of the program that the University of Wisconsin has been conducting over the past few years under the auspices of the Air Force Cambridge Research Center using the compound quartz pendulums developed by the Gulf Research and Development Corporation. The program includes the establishment of four meridional lines of measurements which roughly will follow from Point Barrow, Alaska, down the west coast of South America to Punta Arenas, Chile; from Thule, Greenland, down the east coast of North and South America to Punta Arenas; from Hammerfest Norway, to Capetown, South Africa, and from the Aleutian Islands down the island archipelagoes east of Asia through Australia to Antarctica. To strengthen these measurements, an effort is being made to get observations made with as many other sets of first-order pendulum apparatus as possible, particularly the Cambridge University (England) pendulums which have been used so extensively on earlier measurements throughout the world. This work it is hoped will remove the present ambiguity in international gravity measurements resulting from varying gravity standards being employed. Another phase of the international gravity program, being conducted principally by the University of Wisconsin, is the tightening of the international network of world gravity bases through repeat gravimeter measurements, a program originated under the auspices of ONR.

In the United States, the work of the Committee centers on the preparation of a national gravity anomaly map. This project, which is nearing completion, has been a cooperative venture involving government agencies, universities and the oil industry. The map is to be published by the U. S. Geological Survey and will be a companion map on a scale of 1:2,500,000 to the new geological and tectonic maps of the country that are now in preparation. All observations are being processed with IBM equipment and final data will be available in printed form through the U. S. Coast and Geodetic Survey, which agency has agreed to serve as a national repository. A similar gravity map for Canada is also now in preparation by the Dominion Observatory and is expected to be released this spring.

Of interest from the standpoint of geology and crustal structure is an analysis, now in preparation by the Chairman, of the relation among regional gravity anomalies, geologic structure, and crustal structure as determined from seismic measurements. Results of this study to date suggest that the concept of an elastic crust with sufficient strength to sustain superimposed loads represented by changes in topography, advanced by Gunn, holds for much of the western mountain region. In this area the overall anomaly picture suggests a thick crust averaging about 45 to 48 km in thickness, which is flexed beneath mountains such as the Bighorns and the Uintas. Over the eastern part of the country it appears crustal thickness is much less and varies between 30 and 40 km, with areas of maximum thickness corresponding to areas of structural uplift, and areas of minimum thickness (at least in some localities) corresponding to areas of surface subsidence. This last would imply a situation analogous to steel in tension that has been stretched beyond the yield point. As a test of the above, the University of Wisconsin plans to make seismic explosive-blast studies in selected areas to ascertain if there is corroborative evidence.

Magnetism—It is particularly gratifying to note that the country is being gradually covered more and more by aeromagnetic surveys and that the areas of detailed surveys are being interconnected by traverses flown purely out of scientific curiosity. It also is gratifying to note the success with which aeromagnetic data are being applied in determining the depth of the basement in sedimentary rock areas that are uncomplicated by the inclusion of volcanic horizons. For many areas such as the Coastal Plain regions, the magnetic values appear to offer an economical technique for estimating basement depth with sufficient accuracy for many geologic studies that otherwise would have to wait many years if seismic or drill hole data were to be the only source of information. The present program of the U. S. Geological Survey for working up the large number of cross-country profiles they have taken, as well as the policy of commercial organizations to take such measurements and publish them, can be expected to yield some most interesting and enlightening data concerning near-surface structure.

A map that would be of interest to many geologists is an unpublished one compiled by the U. S. Coast and Geodetic Survey showing the areas of anomalous magnetic declination which must be considered in preparing the smoothed declination charts that are published regularly. The publication of this map would give much valuable information that would aid in both the study of regional geology and also in the correct interpretation of variations in regional gravity anomalies.

Basement study—Through the Committee Chairman, the Committee is cooperating with the Basement Study Committee of the American Association of Petroleum Geologists in compiling all well data involving the basement complex throughout the country. This material is being used to establish a file showing the location of basement wells, depth to basement, type of rock, location of cores, etc. Through the cooperation of the Society of Exploration Geophysicists as well as of this Committee, geophysical data bearing on the basement are also being compiled, so that a fairly complete basement configuration map can be prepared. The last map of this type available for the country as a whole was the one prepared by the Committee in 1939 under the direction of W. T. Thom, Jr., Chairman of the Committee at the time. Since then many new data have become available, and the AAPG Research Committee is to be commended for underwriting this study.

Advancement of geophysics in colleges and universities—As much of the geophysical equipment given to schools either never comes into use or falls into indifferent custody in the course of faculty changes, the Chairman of the Committee proposed to the Geophysical Domain Committee of the American Petroleum Institute that a central respository be set up for lending equipment on a temporary basis to schools having students actively interested in working with such equipment. While no formal program has been established as yet for financing the maintenance of equipment, or for training people in the use of it, for reducing the data, etc., the Committee, through its members, was instrumental during this past year in getting geophysical studies started on regional geological problems on a *pro tem* basis at four institutions. This policy should pay large scientific dividends for the small outlay in funds and time required.

Astronomical studies of interest—The recent work of Gerard Kuiper of Yerkes Observatory concerning the Moon, its surface features and their origin will be of interest to all students of the Earth. As there has been some apparent misunderstanding of his position concerning possible analogies between Earth structure and that on the Moon, Kuiper, at the request of the Chairman, kindly consented to write a short abstract on his findings and views, which is attached.

Department of Geology, University of Wisconsin, Madison, Wisconsin (G. P. W.).

APPENDIX

A REPORT ON RECENT LUNAR STUDIES AND THEIR BEARING ON THE NATURE OF TERRESTRIAL CONTINENTS AND OCEAN BASINS

G. P. Kuiper

The common distinction between the low dark maria and high brighter continents, readily made on lunar photographs, must be refined. The bright areas are of two types: (1) accreted crust, modified by a sequence of impacts that led to the formation of the familiar large lunar craters; and (2) maria or accreted crust, buried by material clearly ejected from Mare Imbrium and a few smaller splash centers. The major mountain ranges (Alps, Caucasus, Apennines, Carpathians) belong in this second category; they seem to be composed of light-colored blocks of crust, mixed with large quantities of darker lava, now solidified, which look somewhat like mud flows.

The recent suggestion by T. Gold and others that the maria are featureless because they are filled with a very deep layer of dust is contradicted by several groups of observations: (1) The maria, seen under very low Sun, show an intricate fine structure, including discrete flows, minor faults, graben, etc. (2) Impact craters situated on the 'shore' lines of maria are often tipped toward the mare, like partly-sunk boats lying against the shore line of a lake. Apparently, the foundations of these crater ruins were melted locally and the ruins have subsided or even submerged. (3) A compelling argument is derived in the next paragraph from the nature of the ridges on the maria. (4) There is no trace of a filling effect of very small craters such as a thick, mobile dust layer would cause. Actually, the maria are beset with hundred of small craters (about 1 km in diameter and smaller), whose numbers and shapes indicate that they are meteoritic in origin. Large craters, (10 to 100 km), as found on the continents, are nearly absent on the maria. These large craters appear to represent an early phase of lunar development, preceding the development of the maria and partly concurrent with it. The maria were probably formed about 4.5 billion years ago.

The maria are of two types: (a) Nearly circular basins, surrounded by mountain rings, that appear to have been caused by very large impacts; they are essentially giant lunar craters; and (b) areas clearly inundated by lava. Intricate systems of low, long ridges occur on all maria, apparently the result of lateral compression which is attributed to cooling and shrinking of the underlying shells. My recent studies have shown that for roughly one-third of their length these ridges have no visible fine structure; another one-third can be seen to have cracks of widths up to several hundred meters running roughly along the crests of the ridges, while the remainder show dikes, usually as continuations of the cracks. The dikes barely protrude above the ridges, and can be seen by their somewhat lighter color and the shadows they cast at very low Sun. The general outline of these ridges is often nearly concentric with the 'shore' lines of the maria, but their detailed structure frequently resembles a twisted rope, that is, with a tendency for an echelon structure. As a result, the individual elements (usually a few km long) are often inclined some 45° with respect to the inferred lines of compression; this is quite understandable dynamically. The ridges and their dike systems are among the most powerful arguments for the view that the maria resulted from melting and subsequent solidification, and are not basins filled with electrically charged mobile dust particles. In principle, the ridges will determine the depths of the maria basins. The curious ridge systems in Mare Nubium and Mare Tranquilitatis show unmistakably the shallowness of these maria and the presence of older bottom topography. Some 15 beautifully shaped volcanos are found in three regions, on shallow maria. These volcanoes are all about 7 to 8 km in diameter measured at the base, and have outer slopes of about 5°, comparable to the slopes of basaltic volcanoes on Hawaii; while all but one show central calderas. In the same regions many smaller volcanoes are present as well.

On the continents no such volcanoes have yet been found, but there are many isolated and rather shapeless 'humps,' each a few km in diameter; examples are found between the craters Schiller and Schickard. These humps have sometimes been regarded as distant splashes from Mare Imbrium; but my recent observations have shown the presence of dikes on these masses, sometimes as many as four. This appears to establish that they are not foreign additions, but probably local extrusions.

The lunar maria differ from the terrestrial ocean basins in that the crust of the maria appears to be of limited depth, as judged by the ridge systems, except perhaps for the central zone of Mare Imbrium (the impact center) where no ridges are present at all. One surmises that the outer layers of the Earth melted much more completely than those of the moon, some 4.6 billion years ago. Two causes for this difference are apparent: (1) the greater heat at the surface of the Earth resulting from convection in the liquid mantle, and (2) the presence of an atmosphere on the Earth, which at that time may have been a much more efficient insulator than at present, owing to the presumably very large water-vapor content prevailing at the high temperatures.

The lunar maria differ further in that they show no clear evidence of lava flows that are substantially younger than the maria themselves. This is indicated by the ray craters which have scattered their white material (probably rock flour) everywhere over the maria; since these craters are as large as the pre-mare craters and much larger than the contemporary meteor craters, of which the maria have their expected share, the ray craters are probably early post-mare in age. (It is very probable that the large craters on the Moon are due not to asteroidal meteorites, but to a ring of small satellites moving around the Earth, which the Moon slowly transgressed in its recession from the Earth due to tidal friction some 10^9 years after its formation, that is, some 4.5 billion years ago). On the other hand, evidence for more recent lava flows does exist in smaller areas, such as eight small regions in the crater Alphonsus.

The lunar continents differ from the terrestrial continents in that the latter appear to be the result of a fractionation process that caused the composition to be no longer representative of the silicate mixture found in meteorites (which presumably resembles that of the bulk of the Earth's mantle). The lunar continents seem to be the old accreted crust, reworked locally by impacts, but in composition presumably similar to the average of the meteorites. This difference, like that between the lunar maria and the terrestrial ocean basins, may be due to the difference in surface temperature of the two planets at the time of maximum melting.

A new photographic lunar atlas is now in preparation based on the best plates available at different observatories.

Discussion of "The Effect of Non-Representative Sampling on Linear Regressions as Applied to Runoff"

BY W. D. POTTER

[*Trans.*, **38**, 333-340, 1957]

N. J. Cochrane (Alliance House, Caxton Street, Westminster, London, S.W. 1, England; received August 12, 1957)—Potter's analysis of the effect of non-representative sampling is salutary but a further complexity may lie in the applicability of extreme-value statistical theory to hydrological problems. Some recent investigations by the writer and others suggest that the prognostications of a Gumbel-type flood analysis can be grossly in error even when the period of the record is several decades. Perhaps the reason is that hydrological events are not all of a random nature. They certainly are not random but demonstrably cyclic in the cases of the Lake Nyasa-River Shire and Lake Victoria-River Nile complexes in Africa, and also in the cases of the Rivers Thames and Severn in England.

J. L. McGuinness and *D. L. Brakensiek* (U. S. Agricultural Research Service, Coshocton, Ohio; received August 28, 1957)—The author is to be commended for bringing to the attention of hydrologists the dangers inherent in the extrapolation of recorded runoff data to other watershed sizes and into other localities. The scarcity of suitable records in most areas of the country, especially reliable records in the smaller size classes, has made this practice rather prevalent. Extrapolations of hydrologic data must always be made as a matter of course but on the basis of the author's study it is apparent that considerable care must be taken to insure reliable results.

In addition to area and location representativeness, one must also consider the representativeness of precipitation factors. This is especially pertinent as the author's P and S ratios and Q values were defined from a probability study of a short period (1938-1948) of record. In other words, for a frequency analysis of a short set of data to have meaning, it must be shown that the years of record are representative of the long-time weather pattern. The author is evidently aware of the need for a representative precipitation sample since in the description of the original study in 1953, he deals at some length with the computation of long-term P and S ratios. At least one other of the author's previous works dealt primarily with this subject [*Potter*, 1949].

As in this paper the period of study is not shown to be of a typical weather pattern, the writers suggest the U-test [*Mann* and *Whitney*, 1947] as a simple, objective method of checking representativeness. For this test, records from a long-term weather station would be used. The following example uses the 60-minute maximum intensities per year for Columbus, Ohio, for the period 1899-1951. The U-test is used to determine whether the frequency distribution of the period 1938-48 is identical with that of the longer period of rainfall record. If it is the same, then the author's conclusions are based on a weather sample which is representative of a much longer period at that location.

First the 53-year record of 60-minute maximum rainfall values at Columbus were ranked in decreasing order. The sum of the rank numbers T was found to be 186 for the 1938-48 period. If the number of years in the 1938-48 period is denoted as $m = 11$, and the remaining years as $n = 42$, then the statistic, U, may be computed as

$$U = mn + [m(m + 1)/2] - T \tag{1}$$

When the hypothesis of the two distributions being identical is true, (for m and n both larger than 8) the random variable U will have approximately a normal distribution with the mean

$$E(U) = mn/2 \tag{2}$$

and variance

$$\sigma_U^2 = mn(n + m + 1)/12 \tag{3}$$

For the Columbus data, $E(U) = 231, \sigma_U = 45.6$, and

$$t = U - E(U)/\sigma_U = 2.43 \tag{4}$$

The probability of a value of t greater than ±2.43 is approximately 1.5 pct. The conclusion would be drawn that the 1938-1948 sample has a different frequency function than the remaining period and therefore the sample period can not be considered a representative period at Columbus, Ohio with respect to maximum 60-minute intensities.

Data were not available to the writers for investigating the representativeness in time of *P* and *S* ratios and *Q* values at other locations.

Manuel A. Benson (U. S. Geological Survey, Washington 25, D. C.; received September 4, 1957)—There are some rather vague conceptions used in this article which seem to need some further thought and clarification. For example, "... the Allegheny-Cumberland Plateau, an area considered to be homogeneous as to physiographic characteristics, ..." The term 'homogeneous' is never defined hydrologically, yet this is vital to the discussion. The *T* factor for each station (in Table 1) shows a considerable range, indicating large differences in slope for the individual drainage basins. The region could not therefore be considered homogeneous with regard to the physiographic characteristic of slope. As shown by the variation in *P* and *S* indices (Table 1) both the rainfall intensity and rainfall storm frequencies show significant variation within this region. Is this region homogeneous with regard to the physiographic characteristics of rainfall? Again, if a region is homogeneous, should it make any difference in which part of the area any particular station is located? Yet, the definition of 'representativeness' is based on sampling with respect to location. It appears to the writer that if the need for representative sampling with respect to location is proved, that constitutes a direct proof of non-homogeneity.

The concept of representativeness as set up here is in general somewhat questionable. The data to be analyzed consist of one dependent variable (the ten-year flood), and four independent variables, namely, the area, the *T*, *P*, and *S* factors. Sampling over the range of drainage area is defined as a measure of representativeness, yet why is it not equally valid to require sampling over the range of the *T*, *P*, and *S* factors? Proper sampling should adequately represent the basic distribution of all variables.

Results of the comparisons of non-representative samples with the entire group or the test sample might be interpreted as follows:

(1) Samples unbalanced as to location lead to regression curves departing from the test curve because of the nonhomogeneity of the region. (If Zones 1, 2, and 3 differ in general characteristics the elimination of data from any one would necessarily give a relation departing from the overall average.)

(2) Samples unbalanced as to size represent arrays in which the range in one of the variables has been reduced. This is obviously true in the case of samples 6 and 7, and effectively true in the case of sample 5. Reduction of the range in one of the variables would be expected to decrease the precision of definition of the regression line.

Statistical methods developed over a long period of years have resulted in an almost universally used measure of the error of estimate in correlation studies. This is the 'standard error.' It includes a correction for the number of lost degrees of freedom associated with the number of variables considered and a correction for the number of items in the sample. The method used here, which computes percentage errors, neglects entirely both of these vital considerations. The computed percentage error for any sample does show results for that sample but is not a measure of the error of prediction. The author states "... they (the distribution-of-error curves) were used as a yardstick to measure the relative accuracy of prediction that might be expected from a general application of each of the regression equations." If a straight line were to be fitted by least squares through three points, a small percentage error might be computed at 67 pct of the sample size. Yet that figure would be useless for prediction purposes, since the standard error of prediction based on three points would most likely be extremely high. Percentage errors for samples of different size, as computed by the author, are not even a relative measure of the accuracy of prediction. Conclusions involving the size of samples are patently inappropriate when based on procedures which neglect the sample size.

There is a need for sampling in making hydrologic analyses, because the vagaries of establishing data-collecting stations frequently produce unbalanced coverage in location, size of area sampled, and other factors. However, sampling must be judicious because there is frequently all too little hydrologic data available. Another alternative is to use all the records but to weight them so as to remove the bias caused by imbalance. This has the advantage that use is made of all the data available.

W. D. Potter (Bureau of Public Roads, Washington, D. C.; Author's Closure)—Cochrane's observations regarding the possible cyclic nature of hydrologic events are undoubtedly true in, at least, some instances. Unfortunately, the meagerness of available data precludes a determination of whether or not this cyclic nature pertains to all such data or is limited only to isolated cases.

The U-test, described by McGuinness and Brakensiek, should prove to be a very useful tool for hydrologists. As pointed out in their comments, the values of P and S, computed for the short period of runoff record, are only used to establish the relation between the ten-year peaks and the rainfall that was their source. To use the original regression equation to estimate a ten-year Q from an ungaged watershed, new values of P and S, based on long-term records, must be used. These values were computed for the Allegheny-Cumberland Plateau and presented as a map showing lines of equal P and S ratios in a later publication [*Potter*, 1954].

Aside from a doubtful admission that sampling might be necessary for some hydrologic analyses, Benson seems to question practically the entire paper.

His first question revolves around what is meant by homogeneous and the degree of homogeneity ascribed to the Allegheny-Cumberland Plateau. Webster defines homogeneous as being, "of the same kind or nature" (not identical) "consisting of similar" (not the same) "parts or elements." Certainly the geology of the watersheds is similar, the Plateau being an eroded peneplain underlain by nearly horizontal strata of sandstone, limestone, and shale. The side slopes are similar since the valleys are all steep sided and V-shaped. The watersheds are also similar in that their soils are shallow and their drainage pattern typically dendritic.

The fact that these physiographic characteristics are similar does not signify that they are identical or that possible differences might not exist between various portions of the area. These differences would have been greater, however, if the comparisons had been between watersheds where physiographic characteristics were dissimilar and it is for this reason that they were limited to one homogeneous area.

It is true that there is a considerable range in the values of T, but this would be true even within the confines of a single watershed since the slope of the stream channels is steeper near the headwater than in the lower reaches. It is also true that there is a considerable range in the rainfall indices P and S, but these can more properly be classed as meteorologic rather than physiographic characteristics.

Benson states that a sample is nonrepresentative when balanced only with respect to location and watershed size without regard to all of the independent variables. I have no fault to find with this statement except that it implies that these requirements were not met in the selection of the representative samples used in the paper. Since, however, the independent variables T, P, and S are very closely correlated with either location, watershed area, or both, it is evident that any sample balanced in these respects is also balanced with respect to those variables.

Benson's third question concerns the use of the standard error as a measure of the error of prediction.

When a random sample is drawn, it is seldom that any assurance can be had as to whether or not it is representative of the population from which it is drawn. The larger the sample the greater the chance that representativeness will be obtained. Likewise, the greater the number of variables involved, the smaller the chance that the sample will be representative. In such cases the standard error, with its built-in corrections for sample size and number of variables, gives the most reliable estimate of the precision that may be expected from predictions based on sample relationships.

If, however, the sample is carefully selected so as to be truly representative of the population from which it is drawn, then the distribution of the sample and population should be the same. Adding to the size of such a sample would not increase its representativeness, since it was already representative. Likewise, the number of variables involved would not affect its representativeness if the entire range of these variables had been sampled.

The above statements are substantiated by the fact that when the 34-watershed test sample was applied to the original regression and to regressions I, II, and III, the distribution of error graphs derived from the average of regressions I, II, and III were practically identical with that derived from the original regression. This was true in spite of the fact that regressions I, II, and III were derived from samples of only 18 watersheds while the original was derived from 51. The computed upper and lower limits of the standard error for the average of regressions I, II, and III was 30 and 23 pct respectively, or an average of 26 pct, while that for the original regression was only 18 pct. If these standard errors had been measures of the precision to be expected, then the distribution-of-error graph for the original regression should have shown a substantially smaller error than that for regressions I, II, and III for all values of per cent of sample. Since, however, all four regressions were based on representative samples, the precision of their estimates was found to be the same.

If relations are established from a sample drawn from selected zones or size groups, then the standard error would be a measure of the accuracy of prediction only for that portion of the population included in those same zones or size groups. Where the relations are based on representative samples, however, the accuracy of prediction remains constant for all portions of the population. For example, regression VI was derived from a sample of 16 watersheds from Zone 3. The computed standard error was 16 pct (average of upper and lower limits). When applied to a sample drawn from Zone 1, however, the error for 68 pct of sample was found to be 34 pct. Likewise, the computed standard error for regression VIII (based on a sample from size group C) was 20 pct. When applied to a sample drawn from size group A, the error for 68 pct of sample was found to be 57 pct. On the other hand, the error for 68 pct of sample for the average of representative regressions I, II, and III was found to vary by no more than three per cent regardless from which zone or size group the sample was drawn.

Finally, Benson suggests that the use of all records would be more advantageous than selective sampling but that such a procedure would necessitate weighting the data to prevent bias due to imbalance. Since the relative merits of these two methods is outside the scope of the paper, I will merely point out that the difficulty with Benson's suggestion lies in a selection of weights that would insure against intuitive selection.

A. HUNTER DUPREE, *Science in the Federal Government—A History of Policies and Activities to 1940*, Belknap Press, Harvard Univ. Press, Cambridge, Mass., 460 pp., 1957, $7.50.

The basic question to which Dupree addresses himself is: By what processes have science and Government developed their mutual responsibilities to each other? His approach to the problem is through a series of interrelated essays on the histories of many agencies, and comments on the reasons for their success or failure in attempting to establish a part of the Federal policy relating to scientific matters. Throughout the book are incidents to support the point that science has meant different things to successive generations, and at any one time it has meant different things to a wide variety of groups. It is the interplay among these various concepts that provides the full historical definition of science. Because the emphasis is on the institutional setting, Dupree's use of the term science includes education, communication, and organization, as well as the creation of new knowledge by research. As such, this is a story both of institutions and of ideas.

Through the patent clause of the Constitution and congressional power over coinage, weights, and measures, science has been in the Government since the beginning in 1789. The following century and a half can be divided rather arbitrarily into four periods of the gradual emergence of science as a function of Government. The earliest is the pre-Civil War period, in which the first six chapters tell the story of Thomas Jefferson's and John Quincy Adams' enlightened attempts to use science for the benefit of mankind; the establishment of the Smithsonian Institution when Congress reluctantly accepted as a gift the estate of the Englishman who never visited this country; the dominance of the Coast and Geodetic Survey; the early exploration and surveys of the West. It was in the succeeding major period, from the end of the Civil War to about 1890, that research expanded in Agriculture, facilitated primarily by the Morrill and Hatch Acts permitting grants-in-aid to land-grant colleges. The event during this period that changed the role of science in Government probably more than any other single factor was the consolidation of the western surveys that resulted in the appearance of John Wesley Powell as a new type of bureau chief.

The conservation movement led by Gifford Pinchot and Theodore Roosevelt dominated the period between 1890 and the World War I and led to the creation of the Reclamation Service, Bureau of Mines, Public Health Service, National Park Service, and Forest Service. World War I provided for the development of relationships between industry and Federal science that have been further strengthened continuously to the present. In the years after the War the role of social sciences expanded through such agencies as the Bureau of Agricultural Economics, the Bureau of Home Economics, and the Tennessee Valley Authority. As Dupree points out, through all the twists and turns of the political history of the United States the policies and activities of the Government in science make a single strand which connects the Constitutional Convention with the National Science Foundation.

Despite the abundance of detailed information and the scholarly documentation of primary sources, this book is not simply a who-did-what sort of historical treatment. Dupree's penetrating insight and analytic interpretation of the events show the logical reasons for developments that have heretofore been obscure. The kind of thought-provoking contribution that he has made to the history of science throughout the book is exemplified by the chapter on the Civil War relating to the genesis of the National Academy of Science. (Essentially the same treatment appears in *The Founding of the National Academy of Sciences—A Reinterpretation* by A. Hunter Dupree in Proc. Amer. Phil. Society vol. 101, No. 5 Oct. 1957.) The usual way of describing the origin of the National Academy is to say that it was created by President Lincoln in 1863 to assist the Government in the Civil War. Dupree's examination leads to the conclusion that the Civil War was merely the occasion and not the cause of the birth of the Academy. The lines of organization had been formulated as early as 1851, and a closely knit group of scientists of the highest prestige worked toward a National Academy from that time onward. When they had succeeded in 1863, their attempt to enter the field of weapons research was almost a complete failure, and it was their losing control of the organization after the War that finally enabled it to survive.

Dupree treats profoundly many topics that have concerned scientific administrators throughout history. For instance, in discussing the development of a scientific program in the Department of Agriculture, he points out that the Department achieved success only after it abandoned the discipline-type organization in favor of a problem-type organization. That is, the problems of growing particular crops or improving animals became the central interest instead of the program centering around chemists who tested various substances, and the Bureau mobilized teams of experts from various disciplines to work on each problem.

Although John Wesley Powell has been one of the most intensively studied figures in American science (T. G. Manning's forthcoming history of the Geological Survey will make the coverage still more complete), Dupree adds an interpretation to his achievements which has not been pointed out so clearly by previous biographers. Following the ideas expressed concerning the development of science in the Department of Agriculture, Dupree recognizes Powell as the personification of a new type of bureau chief able to develop the Geological Survey into an ideal bureau within a short period of time. Some of the criteria of an ideal bureau, as exemplified by these two agencies, are control of flexibility through lump-sum appropriation so that emphasis can be shifted as the problems change in anticipation of need; development of a stable corps of scientific personnel who are competent, loyal, and confident that their work is important to the country; establishment of harmonious relationships with groups such as Congress, other agencies, the American Association for the Advancement of Science, and universities. The conclusions are that science became more effective when its objective was research on specific broad problems by a stable organization centered around the problem rather than the disciplines.

Dupree, formerly at Harvard and now with the University of California, has provided us the most complete and understandable history to 1940 of science in the Federal Government, which deserves thoughtful study by all who are concerned with the force of science and Government in our society; moreover, the 54 pages of bibliography and annotated footnotes make this a most useful reference book on the subject.

William Back

Lettau, Heinz H., and Ben Davidson (ed.) *Exploring the Atmosphere's First Mile*: Proceedings of the Great Plains Turbulence Field Program, 1 August to 8 September 1953, O'Neill, Nebraska; vol. 1, Instrumentation and Data Evaluation; vol. 2, Site Description and Data Tabulation, Pergamon Press, 578 pp., 1957, $20.00 (2 vols.).

These volumes present both the composite panoramic picture and small-scale views of an effort which was unquestionably the most elaborate series of micrometeorological observations ever made. According to the explanatory note introducing volume 1, "The project was conceived and organized by the Geophysics Research Directorate with the primary objective to study the profiles of wind, temperature, and other meteorological quantities in the lower 2000 m (atmospheric boundary layer); the turbulence structure; boundary fluxes of energy, momentum, and moisture; and the physical soil properties affected by diurnal variations of meteorological elements." The site at O'Neill, Nebraska, was chosen in order to approximate closely an ideal micrometeorological site of flat, uniform terrain.

Altogether, 15 universities, scientific institutions, and government services participated cooperatively in the project with logistical support provided by the Air Force. This effort thus represented the pooling of resources of the large majority of the groups undertaking major research in the field of micrometeorology in the United States at that time.

Following the introduction by the editors, which includes their over-all impressions of the program, volume 1 is divided into 7 chapters which discuss in order, the synoptic material, subsoil measurements (including heat transfer at the ground-air interface), interface measurements, mast profile data of 'meaned' quantities, fluctuation quantities, and free air observations. The final chapter is called an appendix and serves as rather a digest of the observational results and includes partial evaluations, largely in terms of derived quantities. Each chapter on instrumentation is divided into a number of sections dealing with the measurement of a particular quantity, for example, soil temperature, or closely related quantities such as radiation measurements. Each individual section begins with a relatively short introductory article by an expert in the particular field setting forth the general significance of the quantity in the total picture and the problems involved in its measurement. Individual scientific articles then follow in which details of the appropriate measurements made by a group are presented by a member or members of that group. These comprise a total of some 59 papers by over one half as many different authors. As might be expected, the relative detail of presentation and error analysis is not uniform among the several papers. For one thing, details of some of the instrumentations had been previously published, and others have been presented separately in the form of Project Reports subsequent to the execution of the Great Plains Program. However, the references seem to be adequate for one wishing to delve deeper into any one of the subjects. In passing it might be of interest to note that several relatively novel instrumentations were on field trial in the program, particularly for the study of wind fluctuations, and the discussions of the findings are sometimes expressed with refreshing candor.

The final chapter of volume 1, the Appendix, will of course be of greater general interest, especially to readers who are not interested in or concerned with the mechanics (and electronics) of measurement. Three sections, all by H. H. Lettau, represent the essence of the integrated immediate returns of the elaborate program. They are, following the numbering system of the volume: 7.3, Computation of heat budget constituents of the earth-air interface; 7.4, Computation of Richardson numbers, classification of wind profiles, and determination of roughness parameters; and 7.5, Summary of non-dimensional characteristics of boundary layer theory.

The material and analyses are not presented in these sections at a particularly elementary level. Therefore, some of the arguments and developments will not be easy to follow without some background knowledge in the specialized field of micrometeorology. Questions or even points of difference of detail with Lettau's interpretations and computations are to be anticipated even among micrometeorologists. For example, this reviewer is skeptical of the validity of the 'inertial subrange' parameters computed and presented in Table 7.5.14 (p. 370). Only a necessary, and not sufficient condition was found (the power-spectral density of turbulent vertical motions varied as the $-\frac{5}{3}$ power of frequency) to show that an inertial subrange did exist in the observed frequency range. This fact is not pointed out in the discussion.

Volume 2 contains two chapters, the General introduction, and Data presentation, and closes with an author index. The introduction has four sections devoted to a general description of the site (including a map of the lay-out of observation sites, topographic maps of the immediate and general regions, and aerial and eye-level photographs), the climatology of the region, and the particular conditions during the late summer of 1953. Also included is a section on the scheduling of observations and giving a summary of the data presentation as well as convenient tables summarizing the measurements and data available. The chapter of data presentation, comprising the bulk of volume 2, gives the bi-hourly tabulation of data and synoptic charts for each of the seven general observation periods which average 25 hr in duration. It is pointed out that it was impossible to publish all of the data obtained but "... a certain amount of raw data is preserved on punch cards at the Atmospheric Analysis Laboratory of the Geophysics Research Directorate ... (and) ... can be made available on request."

It is evident that, in total, the task of reducing the large volume of raw data to tabular form was a considerable undertaking. The editors are to be congratulated for their skillful organization of the material in the two volumes which will add greatly to the practical utility of the work, both as reference material and as a data source. The numbering system of the articles in volume 1 and the data tabulations in volume 2 is particularly good. It was chosen so that the first number and the first decimal indicate the same meteorological quantity in both volumes. For instance, articles dealing with temperature profile instrumentation in volume 1 are numbered 4.2.1, 4.2.2, etc., while the tables in volume 2 giving the profile temperatures in each of the observation periods are numbered 4.2.

The quality of the paper and printing are excellent, no typographical errors were noted and the diagrammatic illustrations are adequate. One discrepancy was found, although there might be others, in that Tables 4.2 of volume 2 do not give the MIT 60-min mean temperatures as stated on page 175, and implied again on page 330 of volume 1. Some minor errors were also noted. The computation of R_i for 04h 35m September 8, 1953, 8-m level, 15-min mean in Table 7.4.2 of volume 1 seems to be in error. Also in Table 5.2.a, page 447 of volume 2 the stress at 22h 35m August 18 at the 3-m level has apparently been given the wrong sign as uw is negative. Another point, which is at least annoying, is that the sign convention relative to the direction of the net radiation flux is not consistent in Tables 3.1 and 7.3 of volume 2.

These volumes are not expected to gain a place on the reference shelves of every meteorologist's personal library. The relatively high price of the work will be one deterrent, but more importantly, the subject matter is (unfortunately?) of considerable interest only to a rather limited audience. As previously implied, its greatest value is two-fold. First, as a reference work for those engaged in, or contemplating micrometeorological measurements as few modern techniques were not tried by one group or another. Second, as a source of data obtained at a nearly ideal micrometeorological site. We can expect comparisons with analyses made of the O'Neill data to appear often in micrometeorological literature for many years to come.

The editors and individual authors have done a commendable job of presenting the facts of the Great Plains Turbulence Field Program. Whether the Program accomplished all of its avowed objectives is not within the scope of this review.

Abstracts of the papers presented at the Thirty-Ninth Annual Meeting, Washington, D. C., May 5–8, 1958 listed in the order of the last name of the first author

BERNICE ACKERMAN (Department of Meteorology, University of Chicago, Chicago, Ill.) *Liquid Water Contents of Tropical Cumuli*—Continuous measurements of liquid-water content made during the 1956 flight operations of the National Hurricane Research Project have been used to determine the magnitude of cloud water and its distribution in tropical cumuli. Cloud water is found to be unevenly distributed in a horizontal plane through the cloud. The location of the area of greatest water concentration appears to be related to the external wind field. Many clouds are found to have regions in which the liquid-water content exceeds the theoretical value computed for moist adiabatic ascent with no water loss. However, the average liquid-water content for a cloud penetration is always less than the theoretical. The data show that the magnitude of the liquid-water content is correlated to cloud dimensions and to vertical displacement from cloud base.

G. N. ALEXANDER (U. S. Geological Survey, Washington 25, D. C.) *Statistical Implications of the Station-Year Problem*—Very few professional statisticians work directly in the field of hydrology. Consequently concepts such as station-year and plotting-position have to be transplanted into statistical language before the statistical model can be constructed. The station-year problem is here conceived as the appropriate method of combining hydrologic records in a space-time field. The limitations due to spatial correlation have been recognized and discussed, and the advantages of combining records to obtain regional values are appreciated, but the procedures are largely empirical. This paper examines some of the statistical and hydrologic problems involved in constructing a rational model.

PAUL A. ALLEE AND B. B. PHILLIPS (Office of Physical Research, U. S. Weather Bureau, Washington, D.C.) *Measured Values of Droplet Charge, Polar Conductivities, and Potential Gradients in Supercooled Orographic Cumuliform Clouds*—The size of and free electric charge carried by the cloud particles in a supercooled orographic cumuliform type cloud have been measured on a mountain top at an altitude of 6600 ft. The charges observed lead to a droplet charge distribution which approaches that of equilibrium predicted by the theory of random ionic diffusion electrification of cloud particles. Simultaneously, the positive and negative conductivities in the cloud and the vertical atmospheric potential gradient at the site were recorded.

R. A. Allen (Office of Meteorological Research, U. S. Weather Bureau, Washington, D.C.) *A Note on Long-Range Prediction*—Long-range prediction is essentially a statistical process, hence it should be applicable to prediction for an individual day just as to prediction of the mean over a longer period. An experimental method has been developed for making a probability forecast of the maximum temperature for July 4, with the initial prediction made at any time prior to May 31 and revised at intervals from May 31 up to July 3. The risk interval in which the forecast might be useful is shown.

Don L. Anderson and W. F. Weeks (Air Force Cambridge Research Center, Bedford, Mass.) *A Theoretical Analysis of Sea-Ice Strength*—A sea-ice model can be constructed from photographs and the phase curve of sea ice. From this model a theoretical strength of sea ice can be calculated using grain boundary and stress concentration considerations. The strength can be shown to depend strongly on temperature and salinity. Density is a controlling factor in very young and very old ice. The theoretical results compare well with experimental results.

H. W. Anderson (U. S. Forest Service, California Forest and Range Experiment Station, P. O. Box 245, Berkeley 1, Calif.), and **R. L. Hobba** (U. S. Forest Service, Washington 25, D.C.) *Forest and Floods in the Northwest*—Floods result from many factors. The basic factors are the meteorological events that precede the flood and the physiographic and geologic characteristics of the watershed. Varying combinations of these factors bring about wide fluctuations in flood runoff. In the watersheds of the Pacific Northwest, where forest land makes up a large per cent of the total watershed area, it was hypothesized that differences in forest condition alone also cause detectable differences in flood runoff. Using methods of multiple regression, covariance, and double-mass analysis, the differences became apparent and measurable when the variations in flood runoff attributable to the other factors were measured and isolated. Forest conditions were expressed as area logged, age and stocking of the stand, and area denuded. The effects on flood runoff were evaluated for three areas of the Pacific Northwest.

J. K. Angell (Office of Meteorological Research, U. S. Weather Bureau, Washington, D.C.) *An Analysis of Routine 300-mb Transosonde Flights from Japan*—Navy sponsored constant level balloon (transosonde) flights launched from Japan on a routine basis during the fall of 1957 and the winter of 1958 are discussed. Individual transosonde trajectories are shown by month, as well as the mean trajectory for each month. The transosonde data and conventional upper-air data are compared and reference made to the use of transosonde data in weather analysis. Flights of particular interest are studied in detail. Statistics of the wind velocities, accelerations, etc., derived from the trajectories are presented.

Carl I. Aslakson (Aero Service Corp., 210 East Courtland St., Philadelphia 20, Pa.) *Geodetic Control in Jungle Areas*—Oil companies are frequently faced with the problem of delineating oil concession boundaries in unmapped areas. Such boundaries are often defined by latitude and longitude lines drawn on outline maps. Usually, time limits are set for defining the concession boundaries which preclude the use of conventional surveying techniques. This paper describes the manner in which Aero Service Corporation employed shoran trilateration and shoran controlled photography for geodetic control in the Peten area of northern Guatemala. This method is commonly known as the SCP or secondary control point method.

David Atlas (Aerosol Physics Laboratory, Geophysics Research Directorate, Bedford, Mass.) *New Evidence of Meteorological 'Angel' Echoes*—New observations of a variety of 'angel' echo phenomena were made during 1957. These may be grouped into four types: (1) echoes from thermal columns below cumulus clouds; (2) mantle-shaped echoes associated with the boundaries of cumulus clouds; (3) layer echoes associated with sharp vertical gradients or minima in moisture aloft; and (4) anomalous low-level echoes believed to be produced by the boundary surfaces between differentially moistened surface air over adjacent cold and warm water. Characteristics of these various angel types will be discussed along with evidence supporting their interpretation. These observations, and those previously reported of sea-breeze angels, constitute impressive empirical proof of the association between angel echoes and meteorologically induced gradients in refractive index. However, it is still not possible to account for the observed angel cross-sections theoretically using 'reasonable' gradients of refractive index. The regular observation of elevated blobby angel layers indicates that conditions are frequently suitable for enhanced forward-scatter beyond the horizon of otherwise line-of-sight electromagnetic waves. Furthermore, the data testify to the feasibility and remarkable foresightedness of Friend's 1939 proposal to use radio reflections for the continuous sounding of air mass boundaries. Indeed, any number of heretofore invisible meteorological processes appear open to dynamic examination by powerful new radar systems such as the AN/FPS-6. The vast applied and research potential of these devices awaits to be exploited.

Thomas S. Austin (Pacific Oceanic Fishery Investigations, Honolulu, T. H.) *Variations with Depth of Oceanographic Properties along the Equator in the Pacific*—The vertical distribution along the equator in the Pacific of temperature, salinity, density, oxygen, and phosphate, sea surface to 1000 m, and the anomaly of the dynamic height of the sea surface and other isobaric surfaces above the 700 decibar surface are shown. The figures, depicting summer and winter situations, include stations from within one degree of latitude north or south of the equator between 110° W and 135° E longitude. The surface of the sea, relative to the 700 db surface, slopes upward, east to west, approximately 0.8 dynamic m; the value for the slope is 5.0×10^{-8} during both summer (July to December) and winter (January to June). The longitudinal pressure gradient does not extend much below the layer of relatively large vertical density gradient. At the depth of $\delta_t = 26.5$, 250–300 m, relatively little east-west slope is evident during either summer or winter.

In the surface layer (sea surface to top of the thermocline), temperatures along the equator are lower in the eastern Pacific during both seasons; the thermocline is comparatively level west of 160° W–180° longitude, sloping upward to the east. Temperatures are appreciably lower and concentrations of inorganic phosphate are higher in surface layer in the eastern Pacific during the summer, both reflecting the seasonal and longitudinal variations in divergence and upwelling. The oxygen minimum, centered at a depth of approximately 450 m, is a continuous feature from 100° W longitude (eastern limit of the profiles) to 160°–170° E longitude with the lowest concentrations in the east (≤ 0.5 ml/l) increasing to 1.5 to 2.0 at the westward limit. West of 160°–170° E longitude, concentrations at 450 m rapidly increase to 3.0 ml/l.

Leslie F. Bailey (2929 Connecticut Ave., Washington 8 D.C.) and Carl Romney (6012 Wilmett Road, Bethesda 14, Md.) *Seismic Waves from the Nevada Underground Explosion of September 19, 1957*—Pn-waves from the Nevada underground explosion were recorded at stations between 181 and 1023 km. When fitted to a linear travel-time curve, the observations gave the relation $t = 8.0 + \Delta/8.0$. Less definite P waves were detected at distances as great as 17.7° in the United States and at a distance of 33.4° at College, Alaska. At many stations strong short-period (0.5 to 1.5 sec) arrivals were recorded which were identified as Lg on the basis of their observed speed of 3.5 km/sec. Lg tended to be most definite on the vertical-component seismograms.

W. B. Bailey (Fisheries Research Board of Canada, Atlantic Oceanographic Group, St. Andrews, N.B., Canada) *On the Dominant Flow in the Strait of Belle Isle*—In addition to the usual tidal currents in the Strait of Belle Isle, there is, at times, a tendency for the current to set in one direction more than in the other. This over-balance of water movement in one direction is termed the element of dominant flow. The possible causes of this flow are attributed to meteorological factors and to others effecting long-period fluctuations in sea level. Very few extended oceanographic observations have been available to illustrate this phenomenon on a grand scale, particularly for a westerly flow. Observations taken in September 1955 illustrate a dominant westerly flow in considerable detail. This dominant westerly flow was associated with the passage of an intense low-pressure area (Hurricane Ione) from the Gulf of St. Lawrence to the Labrador Sea between September 21–23, 1955.

Emanuel M. Ballenzweig (Office of Meteorological Research, U.S. Weather Bureau, Washington, D.C.) *Formation of Tropical Storms Related to Anomalies to the Long-Period Mean Circulation*—By using composite charts of time-averaged means, many details of the role of the large-scale circulation in influencing the generation of tropical cyclones are brought into focus. First, a contrast is shown between generally propitious and inhibiting conditions for genesis in the broad area of the North Atlantic. The formation of tropical storms is shown to be concentrated in five areas in the Atlantic and the longer-period circulation features accompanying tropical cyclogenesis in a few of these areas is next discussed with the help of a series of charts containing rather clear-cut anomalous features. Conditions favorable for the formation of tropical storms are found to differ among the different areas. The composite charts appear to be useful as guides in the preparation of long-range forcasts of hurricane formation, once the mean circulation has been predicted.

Paul B. Barton, Jr. (U.S. Geological Survey, Washington 25, D.C.) and Philip M. Bethke (Department of Geology, Missouri School of Mines and Metallurgy, Rolla, Mo.) *Approximate Single Ion Activity Coefficients from pH Measurements*—Many individual ion-activity coefficients can be determined to the extent that: (1) the glass electrode gives a measure of the hydrogen-ion activity, and (2) liquid junction potentials are negligible. The procedure consists of measuring the pH (from which a_{OH^-} is calculated) of a series of solutions of varying ionic strength which are in equilibrium with a metal hydroxide or oxide. From each of these a 'constant', $K' = [M^{+2}]a^2_{OH^-}$, is calculated. Extrapolation of K′ to infinite dilution gives the activity product constant, $K = aM^{+2} \cdot a^2_{OH^-}$. The individual ion-activity coefficient, $\gamma\ M^{+2}$, is defined as $a_{M^{+2}}/[M^{+2}]$ which in turn equals K/K'. A related procedure using basic salts in addition to the simple hydroxides is used to obtain data for anions as well as cations. Experimental work with zinc and copper sulfates and chlorides thus far lacks the precision of conventional physical chemical studies, but the data are useful in predicting the effect of chemical environment on the solubility of minerals. Further refinement of this technique may lead to an understanding of the mechanism of transport of ore minerals under hydrothermal conditions.

A. E. Beck and J. M. Beck (University of Western Ontario, London, Ont., Canada) *On the Measurement of the Thermal Conductivity of Rocks by Observations on a Divided Bar Apparatus*—Rapid techniques for the preparation of discs of rock and the determination of rock conductivities have been used to make a large number of measurements on both coarse-grained and fine-grained rocks. Methods in which either sets of discs or single discs can be used are described, and the mean values of conductivity found by combining the results in various ways are compared. The modes of the rocks were found by examination of a thin section for the fine grained rocks or by examination of each disc for the coarse-grained rocks. Conductivities computed by the method of Birch and Clark from the modes were compared with the experimentally determined conductivities; the results indicate that, at least for the coarse-grained rocks, the usefulness of the conductivities obtained from divided bar measurements can be seriously questioned. The reliability of methods of saturating porous rocks are also questioned.

Walter C. Beckmann, Archie C. Roberts, and Bernard Luskin (Lamont Geological Observatory, Columbia University, Palisades, N.Y.) *Sub-bottom Depth Recorder Survey of Western Long Island Sound*—The sub-bottom depth recorder (SDR) has proved to be an extremely valuable tool in mapping the sub-bottom geologic structure of water covered areas. The SDR is essentially a high-power, broad-band, low-frequency echo sounder utilizing an electrical spark discharge as a sound source. Penetration of over 450 ft of sediments in over 50 ft of water in Long Island Sound has been achieved. The basement topography and the depth of several horizons within the sediments have been mapped in Long Island Sound in considerable detail from Throg's Neck to Smithtown Bay. The basement slopes gently southeast, exhibiting various east-west oriented features having a relief of several hundred feet. Physical separation of the sound source and receiver permits one to obtain wide-angle reflections with continually varying distance. This permits a direct determination of sound velocities in the sedimentary layers and enables one to correct the SDR records for this sound velocity in order to determine the true depth of the various intermediate horizons and basement.

Hugo Benioff and Frank Press (Seismological Laboratory, California Institute of Technology, Pasadena, Calif.) *Progress Report on Long-period Seismograph Recording*—Extension of long-period response of seismographs has revealed the existence of important energy components with periods beyond 50 sec. These long waves correspond to propagation types not hitherto recognized. Seismograms are shown illustrating (a) surface reflected body waves (PS_3) traversing the major arc, (b) mantle Rayleigh waves R18 with period 600 sec, (c) unexplained low-velocity long waves ($T = 200$ sec), and (d) long-period waves from relatively small shocks. The significance of the presence of long waves in terms of the source mechanism is discussed.

Instruments now in routine operation are: (a) three-component electromagnetic pendulums, $T_0 = 30$ sec, $T_g = 90$ sec; (b) strain seismograph with displacement transducer condenser coupled to 600-sec galvanometer; and (c) ink-writing tidal-strain recorder. Experimental recordings are being made with the following: (a) electromagnetic pendulum Z, $T_0 = 2.5$ sec, condenser shunt, $T_g = 600$ sec, and (b) electromagnetic pendulum Z, E-W, $T_0 = 80$ sec, $T_g = 90$ sec. Long-period pendulums with displacement transducer, condenser coupled to 600-sec galvanometers, are contemplated.

Kenneth O. Bennington (Department of Geology, University of Chicago, Chicago 37, Ill.) *Energy Transfer during Metamorphic Differentiation*—Recrystallization in zones of high stress and crystal growth in high and adjacent low stress zones produce characteristic structurally separated contemporaneously developed mineral assemblages. The diffusing material during differentiation is assumed to migrate as oxides and hydroxides. Energy transfer is evaluated by pro-rating the heat of formation of minerals among their constituent oxide groups proportionally to the heat of solution of the separate oxides. An individual oxide has different relative energy values in each mineral structure. Recrystallization is accomplished by activating the least stable oxide first. High differential pressure releases oxides in non-equilibrium reactions under endothermic conditions. Their escape satisfies volume reduction requirements, subtracting energy which is transferred to the lower-pressure and exothermic-reaction area of deposition. Diffusing material migrates down a pressure gradient creating an opposed thermal gradient which is caused and sustained by the dynamic structure. The thermal gradient decays as structural deformation ceases, retrograde reactions being a measure of its magnitude. Migration of pressure systems may force acid material from former low-pressure zones into basic residual masses of former high-pressure areas producing exothermic reactions adequate to form basalts. Extending this hypothesis to an Earth model provides the interesting implication of a low-temperature core

Louis Berkofsky (Atmospheric Analysis Laboratory, Geophysics Research Directorate, Air Force Cambridge Research Center, Bedford, Mass.) *Some Preliminary Results of Numerical Hurricane Formation Prediction*—A nongeostrophic flow model, in which the latent heat of condensation released through pseudo-adiabatic processes is the only heat source, is devised. An attempt is made to formulate initial conditions which resemble, as nearly as is known, the conditions existing prior to the formation of a hurricane. Using these initial conditions, the equations are solved on the IBM 704 electronic computer. Solutions are obtained with and without the latent heat of condensation in order to assess the importance of the heating for the development process.

Nedavia Bethlahmy (U.S. Forest Service, Pacific Northwest Forest and Range Experiment Station, P. O. Box 4059, Portland 8, Ore.) *Logging and Surface Runoff*—Modern logging has introduced techniques which affect the hydrologic characteristics and behavior of watersheds. These techniques involve the building of truck and skid roads, and the use of fire as a tool in eliminating logging debris. Investigations have clearly shown that roads, improperly located and poorly constructed, increase stream turbidity and disturb regularity of streamflow. The effect of skid roads is not as well understood, but good planning and attention paid to details of drainage may minimize the deleterious effects of this phase of logging. The hydrologic effects of controlled fires have been studied, but much remains to be learned. Severe burns reduce soil infiltration rates, but such burns normally occur on only a small portion of the logged area. The aggregate hydrologic significance of these severely burned areas must still be evaluated.

E. P. Bialecke and A. A. Dougal (University of Illinois, Urbana, Ill.) *Laboratory Measurements of the Recombination Coefficient of Electrons and Ions in Nitrogen Gas at Very Low Electron Temperatures*—The recombination of electrons and ions in ionized molecular nitrogen gas was studied in well-controlled laboratory experiments. A pulsed electrical discharge of very short duration was utilized to ionize the gas. After the initial ionization, the electron gas thermalized with the molecular gas through collisions yielding an electron temperature equal to the molecular gas temperature. The gas temperature itself was controlled and variable throughout the temperature range from 92 to 300°K, which resulted in mean electron energies of 0.01 to 0.04 electron volt. Radio frequency measurements made in the microwave wave-length range were employed to determine the concentration of electrons and ions as the ionization decreased due to electron-ion recombination. The recombination coefficient α is found to be dependent upon gas pressure p and electron temperature $T\hat{e}$. At $T\hat{e} = 92°K$, α is 1.9×10^{-6} cm^3/sec at $p = 0.2$ mm Hg and α increases to 7×10^{-6} cm^3/sec at $p = 1.35$ mm Hg. α was also determined at several intermediate temperatures; at $T\hat{e} = 300°K$, α is nearly constant at 7×10^{-7} cm^3/sec for $0.1 < p < 3.0$ mm Hg.

Francis Birch (Dunbar Laboratory, Harvard University, Cambridge, Mass.) *Composition of the Crust and Upper Mantle in the Light of Experimental Studies of Wave Velocities in Rocks*—A considerable accumulation of laboratory data, including unpublished measurements, are now available for the interpretation of seismic velocities in terms of rock types or of hypothetical mineral assemblages. The data show a systematic variation of velocity with mean atomic volume for minerals and compounds in which ozygen is the principal anion (oxides, silicates, carbonates) regardless of structural type, once intergranular porosity has been eliminated by compression. These measurements, with allowance for the effect of temperature, are compared with seismic velocities for the crust and upper mantle.

A. K. Blackadar (Department of Meteorology, Pennsylvania State University, University Park, Pa.) *Frictionally Induced Momentum Oscillations and Motion Patterns in the United States*—Owing to variations of surface stress, the momentum of the layer below 2500 m goes through diurnal oscillations which vary in phase and amplitude from point to point. The distribution of these oscillations over the United States is shown for a ten-day period, and the convergence patterns are discussed in connection with the diurnal distribution of thunderstorm frequency.

M. Blaik, J. Northrop, and C. S. Clay (Hudson Laboratories, Columbia University, Dobbs Ferry, N.Y.) *Some Seismic Profiles Onshore and Offshore Long Island, New York*—Seismic velocity determinations in shallow layers (less than 2000 ft deep) have been made recently at an experimental location on the Atlantic Coast. Speed layering indicated by seismic reflection and refraction is compared with short-interval borehole velocity measurements. Reflection profiles were obtained both on a barrier beach using multiple geophone arrays and in the adjoining lagoon, in approximately eight feet of water, using bottomed multiple-hydrophone arrays. An unreversed refraction profile was completed on the beach by varying the shooting distance and receiving with a fixed geophone array. A reversed refraction profile was obtained offshore, in about 50 ft of water, using shots at different distances from a bottomed hydrophone. Although the smoothed velocity distribution data may be closely approximated by a linear increase with depth, significant high-speed and low-speed layers are shown by the borehole interval velocity data. Very little of this detail is evident in the beach refraction data in spite of excellent time and distance control. The offshore refraction profile indicates even less about layers with thicknesses small compared to the depth of the deepest refractor encountered. The reflection profiles yield little or no detail in this respect. Many significant differences are noted between the seismic profile velocities and the borehole velocities. The importance of each of the methods is briefly discussed.

Harry F. Blaney (U. S. Department of Agriculture, 1505 Post Office and Court House Building, Los Angeles, Calif.) *Consumptive Water Requirements of Vegetative Cover in River Basins*—Consumptive use of water by natural vegetation and irrigated crops involves problems of water supply, both surface and underground, and watershed management, as well as those of management and general economics of irrigation and multiple-purpose projects. Consumptive use is the principal factor influencing water yield from mountain watersheds for irrigation and other purposes in arid and semi-arid regions. This paper presents data on consumptive use (evapotranspiration) by natural vegetation and irrigated crops, and it indicates how this information, together with climatological data, may be employed to determine consumptive-use requirements for water in river basins.

L. E. Borgman (5701 Carew, Bellaire, Texas) *An Algorithm for the Ocean Wave Forces on Inclined Cylinders*—After a review of the assumptions in the wave force formula for vertical cylinders proposed by Morison, O'Brien, Johnson, and Schaaf (1950), a formula embodying the same assumptions is advanced for the determination of the wave forces on an arbitrarily oriented cylinder. Essentially the x components of the water particle velocity and acceleration in the vertical cylinder formula are each replaced by the component of the vector (velocity or acceleration) which is perpendicular to the cylinder axis and in the plane common to the vector and the cylinder axis. The resulting equation is expressed in vector and matrix notation. A concise computational procedure which allows the use of either variable or constant coefficients is outlined and a sample calculation is provided.

W. F. Brace (Massachusetts Institute of Technology, Cambridge, Mass.) *Indentation and Plastic Properties of Certain Geologic Materials*—Many apparently brittle rock-forming materials become plastic locally under indentation by a hard object. Plastic rather than brittle behavior is due to the high confining pressure imposed locally beneath the indentor. In the indentation, or 'hardness' test, a diamond ball or wedge is pressed into a smooth surface of the test material, providing one or more points on the conventional stress-strain flow curve, corresponding to strains of eight per cent or more. For materials which are isotropic and do not work-harden, the stress at this strain is the yield stress, and it can be calculated approximately. Results obtained for limestone and rock salt are compared with yield characteristics obtained in more conventional tests by Robertson, Bridgman, and others. Indentation may be used to study plasticity of other materials such as ice, anhydrite, and quartz at various temperatures and strain rates.

R. R. Braham, Jr. (Department of Meteorology, University of Chicago, Chicago, Ill.) *Cloud Duration as an Important Parameter in Cloud Seeding*—One of the disturbing aspects of experiments for increasing precipitation through the use of silver iodide smokes or dry-ice pellets is the apparent lack of consistency between the results of basic laboratory experiments and the results of seemingly similar experiments carried out in the atmosphere. Although seeding trials on subcooled stratus largely repeat laboratory results, the results obtained from seeding subcooled cumuli are far from convincing. Cumulus cloud-seeding experiments carried out by the University of Chicago group gave inconclusive results in spite of a very careful control which permitted an assessment of artificially induced rain as opposed to natural rain. Further study has shown that one of the most serious obstacles to assessing seeding effects in cumulus clouds concerns the duration of clouds suitable for seeding.

To be usable for ice-nuclei seeding a cumulus cloud must remain subcooled for a period long enough to permit the ice nuclei to grow to precipitation sizes. Studies of cloud lifetimes showed that the lifetimes of most cumuli in the subcooled state are approximately equal to the time required for seeding to become effective. Therefore, seeding can be detected only in clouds having a longer than average life. It is in such clouds, however, that the probability of natural rain reaches values approaching unity. Because of these circumstances an inordinately large sample size is required in order to find seeding effects. As a corollary, results obtained by seeding a small number of cumuli must be suspect. A new experimental design for controlled seeding of cumuli is suggested.

R. R. Braham, Jr., E. L. Harrington, and T. E. Hoffer (Department of Meteorology, University of Chicago, Chicago, Ill.) *Use of Refractive Index Turbulence for Estimating Mechanical Turbulence in the Atmosphere*—From a series of in-flight measurements supplied by the Air Force, an analysis has been made of fine structure variations of refractive index around a group of about 70 cumulus clouds. The original data were obtained in the vicinity of the Bahamas on June 15 and 19, 1956. The data were evaluated in terms of RI gradients, making use of a mechanical read-out device for determining the differences in RI and time between successive pairs of significant points in the RI trace. Significant points are defined as points of maxima, minima, and major changes of slope. System accuracy permitted evaluation of RI differences with a precision of about 0.1 N unit and horizontal distances (from airspeed and time differences) to about three meters.

Frequency distributions of RI gradients were prepared for each level of flight and for clear air, cloud core, and regions of transition at the cloud boundaries. The standard deviations of these frequency distributions are measures of the intensity of the refractive index turbulence and were found to be different for various levels and positions with respect to the cloud cores. From the standard deviations of the frequency distributions and from representative values of the horizontal distance over which the gradients extended, it was possible to infer a statistic roughly analogous to the 'mixing lengths' of classical mechanical turbulence theory. Such an approach offers promise of providing information about mechanical turbulence on a scale and to a degree of precision hitherto unattainable.

D. L. Brakensiek (Watershed Technology Research Branch, Soil and Water Conservation, Agricultural Research Service, Coshocton, Ohio) and R. K. Frevert (Agricultural Engineering Department, Iowa State College, Ames, Iowa) *Estimation of Storm Surface Runoff by Infiltration Theory*—Equations with antecedent rainfall as the independent variable were obtained for estimating the parameters of the infiltration capacity equation developed by Horton. The data of this study permitted estimation equations to be developed for a Marshall silt loam-corn, small grain, and legume-grass complex. The derived estimating equations together with a superimposing procedure as outlined by Cook were used for estimating runoff from gaged watersheds in the northwest Iowa study area. Comparing estimated rainfall excess with measured runoff indicated reasonable success. Certain points were discussed which might be considered in future infiltrometer tests. In particular, the possibility that the so-called wet infiltrometer run may simulate unrealistic runoff potentials was considered.

Glenn W. Brier and Isadore Enger (Office of Meteorological Research, U.S. Weather Bureau, Washington, D.C.) *Weather Probabilities Several Months in Advance and Possible Operational Use*—As indicated by the recent "Statement on Weather Forecasting" issued by the American Meteorological Society, it is generally believed that forecasts for more than a few weeks or a month in advance have little or no reliability. Therefore, any rational or systematic long-range planning that takes weather into account must be based primarily upon probabilities provided by climatological analysis. The extent to which these normal climatological probabilities can be modified by a particular prediction scheme will determine its operational usefulness. Even though a prediction method has relatively little skill, an analysis of the problem discloses that its potential usefulness is greatest for those operations most affected by rare or extreme events. A few typical series of monthly mean temperatures have been treated statistically to determine whether there is any predictability beyond one month. Preliminary results show promise that quantitative predictions more useful than climatology can be made regarding the occurrence or non-occurrence of an extreme event within periods ranging up to four or five months in the future.

Charles L. Bristor (Joint Numerical Weather Prediction Unit, Suitland, Maryland) *The Effect of Data Coverage on Forecast Accuracy*—Networks of data were simulated by interpolating height and wind from a hypothetically 'correct' analysis at a uniform array of points. The interpolated values were added to random numbers whose statistics are typical of nonsystematic errors of observation, and were then regarded as genuine data. Such artificially constructed 'data' for several networks of different densities were analyzed independently. The differences between these analyses and the hypothetically 'correct' analysis were taken to be representative of the initial analysis error under conditions of varying station density. Numerical forecasts were computed from the different analyses and compared with the forecast made from the 'correct' initial data. Several such comparisons indicate that initial analysis errors do not grow to an important degree so long as the spacing between synoptic reports confines error fields to a scale smaller than that of the synoptic disturbances. However, with data spacing comparable with that over existing regions of poor data coverage, initial errors are amplified twofold in a 48-hour forecast interval.

Further experiments, in which the data were analyzed objectively, were carried out to eliminate inconsistencies of analysis. Limited experiments of the same type are also discussed from the standpoint of baroclinic instability.

W. S. Broecker (Lamont Geological Observatory, Columbia University, Palisades, N. Y.), K. K. Turekian (Yale University, New Haven, Conn.), and Bruce C. Heezen (Lamont Geological Observatory, Columbia University, Palisades, N.Y.) *The Relation of Deep-sea Sedimentation Rates to Variations in Climate*—Variations in sedimentation rates with time have been investigated in mid-equatorial Atlantic core (A 180–74). Measurements of C^{14}/C^{12} ratios, per cent coarse fraction ($>74\ \mu$), and per cent calcium carbonate at frequent depth intervals permit the calculation of absolute rates of sedimentation for each of the major contributors to the sediment. The rates of deposition of both the carbonate and clay fractions are shown to decrease abruptly from the high glacial rate approximately 11,000 years ago. The observed correlation of sedimentation rate with surface ocean temperature and extent of continental glaciation permits the dating of late Pleistocene events by reasonable extrapolations beyond the limits of radiocarbon dating. The beginning and end of the warm period preceding the last cold surface ocean water period are estimated at $\sim$ 150,000 and 70,000 years respectively.

W. S. Broecker and A. Walton (Lamont Geological Observatory, Columbia University, Palisades, N. Y.) *C^{14}/C^{12} Ratios in Fresh Water Systems*—Radiocarbon age determinations on fresh-water carbonate materials are based on the assumption that an accurate estimate can be made of the C^{14} concentration at the time of deposition. C^{14} analyses of materials formed in fresh water will allow this assumption to be more adequately defined and also provide information about the CO_2 cycle in fresh water systems. It has been shown that underwater plants, shells, and fish collected from the river-lake systems of the Great Basin provide an accurate estimate of the C^{14}/C^{12} ratio of dissolved carbonate. In addition, the C^{14}/C^{12} ratio in river waters generally decreases with increasing carbonate content and the lakes have a C^{14}/C^{12} ratio greater than the river water supplying the lake. These data allow an estimate to be made of the rate of exchange of the carbonate in the lake with the CO_2 in the atmosphere. Although some uncertainty is introduced in the result because of the ten per cent increase in the C^{14}/C^{12} ratio in atmospheric CO_2 which has occurred during the past four years, repeated measurements over a number of years will allow more accurate values to be obtained.

Howard Busch and G. Robert Hall (Soil Conservation Service, 6816 Market St., Upper Darby, Pa.) *Land Use Trends of the Brandywine Watershed*—This paper discusses land use changes and trends which have been observed in the Brandywine Watershed (Pennsylvania and Delaware) in recent years. The application of conservation practices, less intensive use of farm lands, urbanization, and other factors which influence sediment yield are presented. Land use data from soil survey maps and Soil Conservation Service records, and from other sources, are used as a basis for the study.

C. M. Carmichael and R. J. Uffen (University of Western Ontario, London, Ont., Canada) *Remanent Magnetization of Some Allard Lake Ilmenites*—In the Allard Lake region of Quebec (lat 52°N, long 63°W) there are numerous deposits of Ilmenite which are known to be reversely magnetized from anomalies in the Earth's magnetic field as measured by an airborne magnetometer. The directions of the remanent magnetic field of samples taken from both negative and positive anomaly regions have been measured using an astatic magnetometer. It is found that there is a wide variation in directions of the remanent fields of these samples. Both normal and reversed samples are found in the same, and apparently homogeneous deposit.

James H. Carpenter (Chesapeake Bay Institute, Johns Hopkins University, Baltimore, Md.) *The Solubility of Oxygen in Water*—The recent measurements of Truesdale, Downing, and Lowden for distilled water were confirmed, except above 30°C where their data were not adequate. Equilibration techniques were compared and violent shaking was found to cause supersaturation of less than one per cent and only at low temperatures. These observations suggest that the anomalous results of Fox are due to causes other than supersaturation created by agitation. A rapid equilibration technique is shown to be valid and recommended for the study of water having an appreciable B. O. D.

(Table for Catanzaro-Gast abstract on p. 510)

Locality	Pb^{204}/Pb^{206}	Pb^{207}/Pb^{206}	Pb^{208}/Pb^{206}
Christmas Lake Pegmatite, Beartooth Range	0.0712 ± 0.0011	1.060 ± 0.010	2.37 ± 0.02
Blackstone Lake Pegmatite, Beartooth Range	0.0702 ± 0.0008	1.047 ± 0.008	2.34 ± 0.02
Glendale Pegmatite, Black Hills	0.0621 ± 0.0007	0.959 ± 0.008	2.20 ± 0.02
Crystal Peak Pegmatite, Pikes Peak, Colo.	0.0604 ± 0.0010	0.921 ± 0.008	2.18 ± 0.03
Morefield Pegmatite, Amelia Courthouse, Va.	0.0553 ± 0.0007	0.860 ± 0.008	2.10 ± 0.02
Bonneville, Wyoming	0.0605 ± 0.0007	0.937 ± 0.006	2.06 ± 0.02
Bob Ingersoll Pegmatite, Black Hills	0.0607 ± 0.0012	0.926 ± 0.010	2.10 ± 0.02

E. J. Catanzaro and P. W. Gast (Lamont Geological Observatory, Columbia University, Palisades, N. Y.) *Isotopic Composition of Lead in Pegmatitic Feldspars*—The study of time-dependent variations in the isotopic composition of lead requires lead samples of known age. Inasmuch as pegmatites can be dated by several independent means and contain microcline with a negligible uranium and significant lead content, they provide an opportunity for the study of these time-dependent variations. Microclines from a number of dated localities have been analyzed. The isotopic compositions are given in the table below. The isotopic compositions of the first five samples are in accord with the model derived from ore leads. The Ingersoll and Bonneville samples appear to contain anomalous lead.

Joseph W. Chamberlain (Yerkes Observatory, University of Chicago, Williams Bay, Wisc.) *The Present State of Speculation about the Origin and Acceleration of Aurora-Producing Particles*—For many years there has been a paradox in the velocity of propagation of solar particles as deduced from delay times between solar and geophysical events compared with the velocity of (at least some) auroral particles that would be required for their penetration to the lower auroral heights. More recently, analyses of the broadened hydrogen lines in auroral spectra have indicated that most of the incident protons initially have speeds considerably less than would be required to reach the bottom of an auroral arc, although there is observational evidence that protons do reach the bottoms of the arcs. Therefore, in order to explain the hydrogen-line data consistently, a dispersion in the velocities of incident protons seems necessary. Further, high-altitude balloon experiments have disclosed x-rays evidently associated with aurorae and magnetic storms and most probably produced by electrons incident with speeds exceeding one-third the speed of light. (In the auroral zone fast electrons are regularly present at rocket altitudes.)

These results suggest that auroral particles are accelerated to high speed in the neighborhood of the Earth. Various acceleration schemes include electric fields, betatron effect, and Fermi's mechanism. An alternative interpretation of the velocity dispersion supposes that the particles travel to earth in a magnetized cloud; individual particles may have high energy through rapid spiraling about the lines of force in the cloud while the cloud as a whole travels through space with moderate speed.

The observation of increased x-ray flux when rayed structures are enhanced might be interpreted in terms of either of two processes for producing rays. The x-rays may simply indicate the entry of fast electrons, which produce rayed features directly. This mechanism is supported by the rough agreement of the electron energy deduced from the Bremsstrahlung x-rays with that required to reach the lower auroral altitudes. As in the case for incident protons, there would probably have to be a velocity dispersion in the electrons to explain the long luminosity curves of rays. Alternatively, rays may be a product of an electric field, which accelerates atmospheric electrons to energies of several ev while it accelerates extraterrestrial electrons to 50 kev. The rays themselves would then arise from the atmospheric discharge rather than from the high-energy electrons.

Sydney Chapman (Geophysical Institute, College, Alaska, and High Altitude Observatory, Boulder, Colorado) *The Terrestrial Implications of Thermal Conduction in the Solar Corona*—The Sun has an outer atmosphere, visible during solar eclipses, called the corona. It is at an astonishingly high temperature, of the order of a million degrees centigrade, whereas the disc of the Sun as we ordinarily see it has a far lower temperature, of a few thousand degrees. The cause of the high temperature of the corona is still uncertain. The corona varies with time, according to the degree of activity on the Sun as shown by sunspots and flares. The coronal gas consists mainly of protons and electrons, the components of sundered atoms of hydrogen, which is the main constituent of the Sun. In addition, there is helium and, surprisingly, a small proportion of very highly ionized metallic atoms. The corona emits x-rays and radio waves. When the Earth's motion brings the Sun nearly in line with cosmic radio sources, the cosmic radio waves are modified; this shows that the corona extends at least several solar radii beyond the Sun.

A study of the temperature and density distribution in the corona has been made by the author on the assumption of a static corona distribution uniformly around the Sun, though eclipse and other photographs show that often the corona has considerable local irregularities in it. The study revealed that the corona must extend over the whole space traversed by the planets, even beyond Neptune and Pluto. It remains hot up to those great distances; at the distance of the Earth, its temperature is of the order 350,000°F, and its density may be 1000 protons and 1000 electrons per cubic centimeter.

The Earth and Moon move through this hot gas, and heat must be conducted from it into the Earth's atmosphere. In the upper ionosphere, the F_2 layer, there is a downward flow of heat, and this appears to be more than is provided by the solar energy of ultraviolet light absorbed in that layer. This downward flow of heat, it is suggested, comes from the hot coronal gas surrounding the Earth. The Earth's magnetic field at high levels hinders this flow of heat in equatorial regions, but the heat can flow freely towards the magnetic poles. Between the F layer and the coronal gas there is probably a layer of nearly neutral atomic hydrogen, several tens of thousands of kilometers thick. In this layer a world wide circulation is likely to be set up that equalizes the flow of heat downwards into the ionosphere.

These studies greatly modify our conceptions of the outer atmosphere, which must extend many earth-radii above the Earth, far beyond where the atmosphere has previously been thought to end. This extended atmosphere is traversed by natural radio signals called whistlers, generated by thunderstorms in the Earth's lower atmosphere; these whistler signals can travel along the Earth's magnetic lines of force to heights of many thousands of kilometers above the equator, and bounce back and forth between the northern and southern hemispheres. Studies of whistlers made in the United States tend to support these new Ideas about the Earth's outermost atmosphere. Further support is given by studies of the zodiacal light.

J. E. CHAPPELEAR (Shell Development Company, Houston, Texas) *The Calculation of Wave Forces on Groups of Vertical Cylinders*—A method of calculation of wave forces on groups of vertical cylinders subject to wave action is presented. The assumptions employed are: (1) The assumptions of boundary layer theory are correct; that is, the effect of the viscosity is confined to regions very close to surfaces and elsewhere we have potential flow; (2) the ratio of the wave height to wave length is small (Airy theory); (3) the ratio of the wave length to the various dimensions of the configuration of the cylinders (the center to center distances) is large; and (4) the ratio of the center to center distances to the various radii is large. The calculation of the potential flow velocity distribution is then made. The result obtained is that only the magnitude of the velocity distribution and the location of the stagnation points are changed from the potential flow distribution around a single cylinder. By arguing that similar configurations should produce similar effects, it is then possible to calculate geometrical correction factors for the drag and inertial coefficients for a single cylinder. Certain examples involving a small number of cylinders in simple geometrical arrays are presented to illustrate the application of the method, and a brief discussion of the experimental evidence is given.

EDWIN J. CHERNOSKY (Geophysics Research Directorate, Air Force Cambridge Research Center, ARDC, Bedford, Mass.) *Geomagnetic H Intensity before and after a Disturbed* (*5D*) *Day*—The values of the magnetic horizontal component intensity H for days of given activity relative to those of selected reference days are studied. The reference day is each of five magnetically most disturbed (*5D*) days of each month that is not immediately preceded by another *5D* day. The difference in H between the reference day and another selected day is allocated to a group designating the number of days intervening between the two days, then studied. The other selected day is chosen in different tests, as being (a) one of the five most quiet (*5Q*) days (b) another *5D* day. The means of each group of any type days from 14 days before to 14 days after the reference day are examined also. In the Cheltenham data (1927–30) the H values are found to be higher in the two or three days preceding the reference day than in almost any of the following 14 days. The post-disturbance increase in H occurs only for the first eight or so days. Since the horizontal intensity is greater just before magnetic disturbance than in the following 14 days, either (a) H does not completely recover within the 14 days or (b) H increases in the days just prior to most disturbance decreases in H and the increase is an integral part of the disturbance mechanism. As disturbances most frequently follow themselves in less than 14 days, with corresponding recovery times, the alternative statement (b) is supported, and thus requires serious consideration.

LLOYD A. CLARK (McGill University, Montreal, Canada, and Geophysical Laboratory, Carnegie Institution of Washington, Washington, D.C.) *Phase Relations in the System Fe-As-S*—The phase relations in the Fe-As-S system at 600°C, studied in rigid silica tubes where a vapor phase is always present, are as follows: A liquid field extends along the S-As join from 100 to 22.8 ± 0.2 weight pct sulfur. An extensive pyrite-liquid field and a narrower pyrrhotite-liquid field are separated by the three-phase triangle pyrite-pyrrhotite-liquid in which the composition of the liquid is approximately 34 pct sulfur, 66 pct arsenic, and <0.1 pct iron. In the assemblages pyrrhotite-arsenopyrite-liquid and arsenopyrite-arsenic-liquid the compositions of the liquids are similar, and are close to the point of arsenic saturation. Arsenopyrite-arsenic-loellingite ($FeAs_2$), pyrrhotite-arsenopyrite-loellingite, pyrrhotite-loellingite-FeAs, pyrrhotite-FeAs-Fe_2As, and FeS-Fe_2As-Fe are also stable assemblages. The phases FeAs and Fe_2As are not found in nature. Many of the three-phase assemblages are presumed to be separated by very narrow two-phase regions whose limits have not so far been accurately defined. Pyrrhotite and loellingite have small fields of ternary solid solution. With increasing temperature between 650° and 750°C first arsenopyrite, and then pyrite, becomes unstable. At temperatures below 450° to 500°C the assemblage pyrite-arsenopyrite becomes stable. Arsenopyrite is synthesized in the presence of excess arsenic and a S-As liquid. Variations in the arsenopyrite unit cell dimensions indicate a limited variation in the composition of this phase.

W. E. COBB AND GILBERT D. KINZER (Office of Physical Research, U.S. Weather Bureau, Washington, D.C.) *Laboratory Measurements of the Growth of Cloud Droplets*—Water droplets initially two microns in radius were held stationary for observation in an upward streaming cloud and were found to grow by accretion. The rate of increase in the radius of individual droplets was measured from four to 65 microns. The free water content and the temperature of the parent cloud were approximately 3.5 gm m^{-3} and 22°C, respectively. Two types of distributions were employed: the first with 80 pct of the free water contained in droplets 5.5 to 8.0 microns in radius; and the second with the free water distributed more widely among droplets 3.9 to 10.4 microns in radius.

W. COMPSTON AND S. EPSTEIN (California Institute of Technology, Pasadena, Calif.) *A Method for the Preparation of Carbon Dioxide from Water Vapor for Oxygen Isotope Analysis*—A method is described for the preparation of carbon dioxide from small amounts of water (ca. 10 mgm) for oxygen isotope analysis. Water vapor is reduced by a mixture of iron and carbon at 500°C, which releases hydrogen without producing a significant amount of carbon monoxide. The iron oxide thus formed is then reduced by the carbon in the same furnace by raising the temperature to 1000°C, and the resultant carbon monoxide catalytically converted to dioxide over nickel. The method has been applied to a determination of the isotopic fractionation factor at 25.4°C between liquid water and carbon dioxide gas. The value found, 1.0407 ± 0.0003, is in good agreement with a determination by an independent method, 1.0410 ± 0.0002. Preliminary data for a second application, study of the isotopic composition of atmospheric water vapor, is also given.

L. F. Conover (Hydrologic Services Division, U.S. Weather Bureau, Coral Gables, Fla.) *Sub-Tropical Clouds as Shown by Time-Lapse Photography*—The behavior of some sub-tropical clouds is shown by 16-mm time-lapse, color photography. Included is the life cycle of a precipitating cumulus as it grows through a stable environment only to be quickly dissipated; the formation of a strato-cumulus deck at twilight; the evaporation of cumuli as they reach the coastline before noonday heating changes the cloud regime; rotation within cloud streets; a cumulo-nimbus shaft showing rotation and the turbulence of the underside of a roll cloud.

H. H. Cooper, Jr. (Ground Water Branch, U.S. Geological Survey, Tallahassee, Fla.) *An Hypothesis Concerning the Dynamic Balance of Fresh Water and Salt Water in a Coastal Aquifer*—Explanations of the dynamic equilibrium between salt water and fresh water in a coastal aquifer commonly assume that the salt water is static. A consideration of some observed phenomena indicates, however, that the salt water moves in a continuous cycle from the sea to the zone of diffusion and back to the sea. This cycle acts to lessen the extent to which salt water occupies an aquifer. The cycle is believed to be energized principally by the to-and-fro motion of the water resulting from ocean tides, fluctuations of fresh-water head, and other forces. The cycle becomes effective as some of the salts in the sea water are transferred to the seaward-flowing fresh water through the process of dispersion in the zone of diffusion. The sea water, lightened by loss of some of its salts, thereupon returns along an upward path to the sea.

Robert M. Cunningham (Aerosol Physics Laboratory, Geophysics Research Directorate, Air Force Cambridge Research Center, Bedford, Mass.) *Details of Atmospheric Structure in and Around Bahaman Cumulus*—Measurements of temperature and humidity with high response equipment (vortex resistance wire thermometer and microwave refractometer) are presented and discussed. These measurements were taken from a B-29 aircraft flying in and around island and ocean cumulus congestus in the Bahamas. Measurements in the short growing stage of cumulus and cumulus bubbles are compared with the dissipating stage. The quasi steady upward flow under the cloud system is described and tentatively related to the periodic almost explosive growth of some of the cumuli.

Leo R. Davis and Otto E. Berg (U.S. Naval Research Laboratory, Washington 25, D.C.) *Rocket Measurements of the Electron and Ion Fluxes in an Aurora*—Energetic ions and electrons have been detected on a rocket flown through a visible aurora. The rocket was fired at 22h 19m CST on January 25, 1958 at Fort Churchill, Canada. The rocket reached a peak altitude of 178 km and passed through a region of the sky covered by a diffuse surface of intensity I. The instrumentation included three scintillation counters, one which measured the total energy flux of electrons of energy greater than 8 Kev and ions of energy greater than about 30 Kev, one which measured the flux of electrons of energy greater than 8 Kev, and one which measured the flux and energy spectrum of ions having energies greater than about 30 Kev. The following results were obtained. (1) The electron flux about 120-km altitude was 1 to 2.5 (erg cm^{-2} sec^{-1} $sterad^{-1}$) and few if any of the electrons penetrated below 85 km. (2) The ion energy flux was about one-hundredth the electron flux, consisted of ions having energies between 50 and 300 Kev, and was absorbed between the altitudes 96 and 112 km. Preliminary analyses of the directional behavior of the particle fluxes above 120-km altitude shows that both the electrons and ions were roughly isotropic over the upper hemisphere.

Aniruddha De (Princeton University, Princeton, N.J.) *Observations on the Deformation Lamellae in Quartz of Four Indian Tectonites*—Well developed deformation lamellae in quartz of two deformed pebbles from a meta-conglomerate, and a quartz-mica schist from Kharsawan, and of a calcareous quartzite from Darjeeling, India, have been studied. The measured angle between optic axis and lamella pole of each grain show that commonly lamellae form at 10° to 15° from the basal plane, as also near ω and d planes of quartz, while lamellae near s, x and m may also be represented. This angle has typical characteristic values for different optic axes maxima in two specimens; the optic axes maxima for grains with and without lamellae in one specimen are mutually exclusive. Crystallographic relation of a lamella tested by another lamella or fracture occurring in the same quartz grain show that the majority of the lamellae could be assigned to $[11\bar{2}0]$ or $[10\bar{1}0]$ zones. The angle formed by two lamellae poles at optic axis in a quartz grain might be 0°, 30°, or 60°; when this is 0° the lamellae have a common direction in the basal plane, which might serve as a common glide line. The variations in the orientation of deformation lamellae with different optic axes pattern suggest that the pre-existing optic axes orientation and the spatial orientation of the lamellae forming stress determine the angular distance of the resulting lamellae from the optic axis.

Hal P. Demuth (U.S. Coast and Geodetic Survey, Washington 25, D.C.) *Applications of the Tellurometer*—This paper will discuss applications of the Tellurometer to specific projects in the U.S. Coast and Geodetic Survey. The project on Atka Island, Alaska will be presented, as well as the present work in Virginia and Maryland on the Federal Highway Program. Some information concerning the accuracy of the instrument both on single-line measurements and traverse lines will be discussed.

Robert B. Dewey (Department of Geology, University of Chicago, Chicago 37, Ill.) *Traction at Wave Velocity Discontinuities*—Experiments have been done to examine a mechanism of producing traction at an interface because of surface waves in that interface. Results showed that the medium of lower wave velocity moved toward the source of retrograde Rayleigh waves. More complex wave systems in a brass plate overlain by incompetent materials such as mixtures of sand and kaolin or finely ground talc produced a number of flow systems and structures among which were low-angle thrust faults. Since the whole fault surface is, in this model, the motor or source of traction, there was no tendency of the thin hanging wall to fold or deform. Thrust produced folds in talc accompanied by differentiation of the talc-air mixture into thin layers of more compacted talc separated by lenticular bubbles of air. These occupied fold cores. These experiments are interpreted as a possible mountain building mechanism.

F. W. Dickson (Division of Physical Sciences, University of California, Riverside, Calif.) *Zone Melting as a Mechanism of Intrusion: A Possible Solution of the Room and Superheat Problems*—Fugitive components (chiefly water) of rock melts, subjected to pressure gradients induced by gravity, diffuse toward lower pressure regions. Melt at the base of a magma column loses water, raising the freezing temperature. Melt at the top gains water, lowering the freezing temperature. Crystallization of minerals at the base releases energy which migrates upward with fugitive components. Country rock surrounding upper portions of the column, subjected to high water pressures at high temperatures, liquifies. The zone melting rises in the Earth's crust followed by the zone of crystallization, which approaches and eventually reaches the liquid-country rock interface in cooler parts of the crust. The process stops because of heat loss or endothermic reactions involving country rock. Efficient use of the original energy has allowed the passive emplacement of a column of plutonic rock, with only a part of the column having been liquid at any given time.

R. R. Doell (Massachusetts Institute of Technology, Cambridge, Mass.) *Paleomagnetic Interpretations*—Recent paleomagnetic pole determinations combined with previous studies may now indicate the following: (1) No continental drift has taken place since the lower Eocene, with little evidence for such drift since the Permian. (2) The 'dipole' hypothesis concerning coincidence of magnetic and axial poles might be questioned. (3) There is a strong need for very careful stratigraphic control in future paleomagnetic studies.

Ralph J. Donaldson, Jr. (Aerosol Physics Laboratory, Geophysics Research Directorate, Air Force Cambridge Research Center, Bedford, Mass.) *Radar Echo Characteristics of Hailstorms and Other Severe Thunderstorms*—Thunderstorms within range of the Blue Hill (Milton, Mass.) CPS-9 radar during 1956 and 1957 were examined quantitatively for echo characteristics capable of identifying storms with hail or damaging winds or both. Reports on surface conditions were received from a network of over 300 volunteer observers. Each reported storm experience was associated, when possible, with the maximum height and maximum radar reflectivity of the particular echo found at the time and place of the storm experience. Reports of hail and damaging winds were associated with a significantly higher average of echo height and radar reflectivity. Although there was no dichotomy in echo features between reports of hail and those with no hail, a useful estimate of the probability of hail was derived from a consideration of both maximum echo height and maximum radar reflectivity. Furthermore, the most severe damaging windstorms and tornadoes were found in the region of high hail probability.

William L. Donn and William T. McGuinness (Lamont Geological Observatory, Columbia University, Palisades, N.Y.) *Seiches in Grindavik Harbor, Iceland*—As part of the IGY Island Observatories program, a conventional tide gage was installed in Grindavik Harbor. The coastal configuration and harbor dimensions are such that the harbor acts as a natural model basin undergoing a 12-ft range in water level twice daily. The period of the ever-present seiche is a function of water level and varies from 4 to 11 minutes with each tide cycle. Observed and theoretical periods correlate very well for the tide range at Grindavik. The amplitude of the seiche is a function of wind direction and intensity with maximum amplitudes occurring when the wind is parallel to the long dimension of the harbor channel. Oscillations of longer and more irregular period occur occasionally at higher stages of the tide. These can be explained by the seiche involving the large flooded shoal area in back of the harbor.

Frederick J. Doyle (Ohio State University, Columbus, Ohio) *Place for Geodesy in the University Curriculum*—Education in surveying, geodesy, and photogrammetry has traditionally been included in civil engineering. During the past several decades the increasing technology in civil engineering has required that courses not directly applicable be diminished, or dropped, from the curriculum. Foremost among these casualties have been courses in geodesy. This trend is continuing, so that today it is impossible to obtain a comprehensive education in geodesy within the confines of a civil engineering department anywhere in the country. To meet this need there is a requirement for a curriculum in the mapping sciences which would be separate from, and on a par with that of civil engineering.

Maurice Dubin (Air Force Cambridge Research Center, Bedford, Mass.) *Measurements of Meteoritic Impacts on Explorer I*—The first satellite launched in the United States during the International Geophysical Year contained an impact microphone to detect collisions of micrometeorites with the cylindrical shell of the satellite. The physical basis of the experiment and a description of the experiment is presented. The objective of the experiment is the measurement of the spatial density of interplanetary matter in the vicinity of the earth by measuring the mass influx of material onto the Earth's surface. The calibration of the equipment to determine its overall sensitivity is described. A very limited amount of telemetered data has been received and examined. These data have been used in the computation of preliminary value for the influx rate of cosmic dust upon the Earth. A comparison of this measurement with values determined by indirect methods will be made. The possible geophysical significance of these measurements will also be reviewed.

Laurence E. Eber and Oscar E. Sette (Bureau of Commercial Fisheries, U.S. Fish and Wildlife Service, Stanford, Calif.) *Indices of Variations in Strength of Atmospheric Circulation over the North Pacific Ocean*—A recent activity, Ocean Research, has been started on the Pacific Coast by the U.S. Fish and Wildlife Service for studying the large natural fluctuations in the abundance and availability of our major ocean fisheries. While defining the problem lies in the field of fishery biology, its solution lies mainly in the domain of oceanography. The study of oceanographic variations is logically inseparable from the study of meteorological variations, and the latter occupies a prominent place on our program. Monthly mean sea level pressure charts have been used to study ocean-wide fluctuations in atmospheric circulation. Pressure gradients at 36 locations oriented with reference to the principal branches of the ocean circulatory system were measured from the charts for a 32-year period. Mean monthly means and standard deviations were computed to determine the seasonal range and variability of gradient values in different regions. Smoothed time series of the data suggest stronger northerly geostrophic wind components on the eastern side of the Pacific for the past decade as compared with earlier years. No evidence of trends was found for the westerlies or trades. Correlation coefficients were computed which compare fluctuations in gradients representing the westerlies with those in other parts of the Pacific.

Floyd C. Elder and Donald J. Portman (Willow Run Laboratories, Engineering Research Institute, University of Michigan, Ypsilanti, Mich.) *Some Measurements of Atmospheric Radiation at Colorado Springs and at the Summit of Pikes Peak*—In September 1956, some continuous measurements of atmospheric, terrestrial, and solar radiation were made near Colorado Springs, Colorado. Simultaneous measurements of total hemispheric radiation were made at the summit of Pikes Peak. A direct measure of the downward flux of radiation from the atmospheric layer below the elevation of the peak was thus obtained. Radiosonde observations, taken at six-hour intervals throughout the period, provide data for computation of the downward flux of radiation from both the total atmosphere and from the atmospheric layer below Pikes Peak through the use of radiation diagrams. A comparison between the measured and computed values of radiation is presented. Instrumentation is described.

William P. Elliott (Atmospheric Analysis Laboratory, Geophysics Research Directorate, Air Force Cambridge Research Center, Boston, Mass.) *The Area within a Concentration Isopleth for Diffusion of SO_2 from a Continuous Point Source*—Concentration measurements taken in the summer of 1956 during Project Prairie Grass were analyzed to find the area within selected concentration isopleths. An empirical relationship between these areas and the value of the concentration, adjusted for source strength and mean wind speed, was determined. This analysis yields an exponential relationship between area and adjusted concentration. The coefficient and the exponent are both related to atmospheric stability in a quasi-predictable fashion.

Isadore Enger (Office of Meteorological Research, U.S. Weather Bureau, Washington, D.C.) *The Period of Time Required to Determine a Daily Normal*—Estimates of the daily normal are made by varying the number of years used to compute daily means and the number of days over which to smooth them. The estimates are then used as climatological 'predictions' one, five, and nine years ahead. The estimate making the best 'predictions', as measured by the root mean square error, is taken to give the optimum period of time to determine a daily normal. Daily maximum temperatures at ten stations in the United States are analyzed in this fashion and the results presented in a series of charts. Some remarks on trends and singularities are made.

Edward S. Epstein (Pennsylvania State University, University Park, Pa.) *The Three-Dimensional Field of Motion in the Lower Stratosphere*—Case studies of the fields of vertical motion in the lower stratosphere have been made by means of an improved version of the adiabatic method. The relations between vertical motion and horizontal flow are described both north and south of the stratospheric warm belt. An attempt to attribute explosive stratospheric warmings entirely to dynamic instability is also described.

Oskar Essenwanger (National Weather Records Center, U.S. Weather Bureau, Asheville, N.C.) *Frequency Distribution of Precipitation in a Logarithmic Scale*—The linear scale is often used for frequency distributions of precipitation data. The statistical approach for these distributions is briefly discussed and compared with results obtained using a logarithmic scale. The latter permits more precise climatological description and understanding of precipitation frequency. Fifty years of Asheville, North Carolina, precipitation record (hourly, six-hourly, daily, monthly, yearly amount) serves as a sample. The theoretical statistical reasons for using a logarithmic scale are also briefly discussed.

E. L. Fireman (Smithsonian Astrophysical Observatory, Cambridge 38, Mass.) *A^{39} in the Sikhote-Alin Meteorite and Its A^{39}-A^{38} Age*—The radioactive isotope A^{39} (260-year half life) is measured in the Sikhote-Alin meteorite which fell in February 12, 1947. For the dated fall the A^{39} can be combined with its A^{38} content to give a measure of its cosmic-ray exposure time. Two Sikhote-Alin samples (7g and 50g) gave 4.8 ± 0.3 A^{39} decays/g day with the activity proportional to the weight. This is the first measurement of A^{39} in a meteorite. No A^{39} is detectable in the Carbo meteorite. Two Carbo samples (6g and 30g) gave 0.05 ± 0.15 A^{39} decays/g day. The He^3 content of Sikhote-Alin was measured to be 4×10^{-7} cc/g; the He^3 content of Carbo was measured to be 4×10^{-6} cc/g. The A^{38} content is approximately $1/12$ of He^3 content. If the assumptions of equal A^{39} and A^{38} cosmic-ray production and constant cosmic-ray bombardment are made, an A^{39}-A^{38} age of 0.5×10^9 years is obtained for Sikhote-Alin. The large He^3 content of the Carbo meteorite combined with its lack of A^{39} activity indicates that it must have fallen more than 2000 years ago.

Irene Fischer (Army Map Service, Washington 25, D.C.) *A Tentative World Datum from Geoidal Heights*—From all astro-geodetic material available at present geoidal heights were computed on 1927 North American Datum for the western hemisphere from Canada to

Chile, and on European Datum for the eastern hemisphere from Great Britain to Japan and from Scandinavia to South Africa. Improved reference ellipsoids were determined under various conditions for each hemisphere by the least squares method. The Columbus Geoid, gravimetrically derived by W. A. Heiskanen, was used to connect the astro-geodetic systems of the two hemispheres. By minimizing the differences between the astro-geodetic and gravimetric geoid elevations at 75 points in the western hemisphere and 127 points in the eastern hemisphere, a theoretically absolute orientation based on the Hough ellipsoid was determined, leading to a tentative World Datum. Two incidental conclusions were drawn from the map of geoid contours on the best fitting ellipsoid: triaxiality is refuted; a remarkable correlation appears between the shape of the geoid and the area of pleistocene glaciation in Fennoscandia and North America.

Robert G. Fleagle (Department of Meteorology and Climatology, University of Washington, Seattle, Wash.) *Comments on Turbulent Transfer at the Sea Surface*—Certain difficult problems are encountered in measuring temperature, humidity, and wind speed over the sea surface. A field program has been developed which minimizes these difficulties to the extent that consistent profiles in the height range between one-half and three meters have been obtained. Within this range the distributions of vapor pressure and humidity are closely logarithmic under lapse, neutral, and inversion conditions with wind speeds ranging from about two to seven meters per second.

Irving Friedman and Robert L. Smith (U.S. Geological Survey, Washington 25, D.C.) *The Hydration of Obsidian Artifacts*—The hydrated layer found on the surface of natural obsidian is thought to be the result of hydration under surficial conditions. To test this hypothesis, obsidian artifacts from dated archaeological sites were examined, and the thickness of the hydrated layer measured. Since the surfaces of the obsidian were freshly exposed by the artifact makers and then allowed to hydrate under surficial conditions, it was felt that these objects represented a controlled lab experiment stretching over many thousands of years. The artifacts were thin sectioned and the hydrated rim, which is bi-refringent and of higher index than the body of the material, was measured under the microscope. Material 500 years old (Chorrera site, Ecuador) shows a rim about one micron (±10 pct) thick; 2000 years old (Hopewell site, Ohio), 3.9 microns; 9000 years old (Danger Cave, Utah), 7.7 microns; 12,000 years old (Shalidar, Iraq), 8.9 microns; 27,500 years old (Iraq), 11.1 microns. The data fit the diffusion law $X = Dt^{1/2}$ where $D = 2 \times 10^{-18}$ cm^2/sec. The data suggest that the measurement of hydrated rims of obsidian artifacts may result in an archaeological dating method. It also proves that the hydration of obsidian under surficial conditions can be geologically important, as has been suggested by Ross and Smith and by Friedman and Smith.

Tetsuya Fujita (Department of Meteorology, University of Chicago, Chicago, Ill.) *Analysis of the Fargo Tornado of June 20, 1957*—About 40 pictures of the Fargo tornado and associated storm clouds were collected. These were taken at the time of the storm from 20 locations, which were visited afterward in order to fix their geographical positions and to obtain the direction angle of the funnel viewed from each spot. After the organization of the pictures, it became evident that the funnel dropped down from the base of a rotating cloud, two to five miles in diameter. Attention was paid to the tornado-bearing clouds which produced at least three tornadoes while moving eastward for a distance of 50 miles. The funnel of the Fargo tornado was cone-shaped until it reached maturity, and changed into a rope-like funnel in its dissipating stage. Successive changes in the shape of the storm system will be discussed in detail.

Tetsuya Fujita (Department of Meteorology, University of Chicago, Chicago, Ill.) *Precipitation and Cold-Air Production in Thunderstorm Highs*—A proposed mechanism of cold-air production caused by precipitation is presented. The study revealed that a dome of cold air was produced by the evaporation of rain drops falling beneath the cloud base. A quantitative relationship between the evaporated rain and the produced excess mass of the cold air was obtained, which revealed that the mass is proportional to the product of the amount of evaporation times a coefficient. This coefficient is a dimensionless number which varies between 1.00 and 0.00 according to the lapse rate of the atmosphere beneath the cloud base. Results of meso-analysis of squall lines and thunderstorms were used in order to estimate the actual amount of evaporation. The mass ratio of the evaporated rain to the surface rain was found to be 50–100 pct or more for a system in western Texas, but only 10 pct for a squall line in Louisiana.

Paul W. Gast (Lamont Geological Observatory, Columbia University, Palisades, N. Y.) *Isotopic Abundance of Sr^{87} in the Earth and Meteorites*—The isotopic abundance of Sr^{87} has been determined in a number of dated rocks covering a time span of almost three billion years. The initial Sr^{87} abundance was found from the age and present-day isotopic ratio. The rate of increase of this initial abundance corresponds to a Sr/Rb ratio of ten or more for the crust and upper mantle. New determinations of the strontium and rubidium content of some composite rock samples concur with a Sr/Rb ratio of about 10. The Sr/Rb ratio reported for chondrites is about three. Thus there is significant difference in the terrestrial and chondritic Sr/Rb ratio. This difference is interpreted as the result of volatilization and loss of alkali metals during the formation of the Earth.

W. Lawrence Gates (Department of Meteorology, University of California, Los Angeles, Calif.) *On the Estimation of Vertical Motion at the Tropopause*—On the basis of an earlier dynamical model assuming constant but different stability in the troposphere and stratosphere, the internal boundary conditions lead to a simple relationship for the large-scale vertical motion at a material tropopause. This relationship is analyzed in terms of typical atmospheric structure, and is applied to a synoptic example. When taken together with other dynamical estimates of mean tropospheric and mean stratospheric vertical motions, it allows an estimate of the three-dimensional vertical motion field to be made, and serves as a first approximation to the tropopause deformation.

Robert C. Gentry (National Hurricane Research Project, U.S. Weather Bureau, West Palm Beach, Fla.) *Use of Winds Inside the Strong Vertical Circulation of Hurricanes to Predict Storm Movement*—The mean resultants of winds measured by reconnaissance aircraft in each of the four quadrants of a hurricane at a single level are related to succeeding 24-hour movement of hurricanes. Resultants computed at radii varying from 30 to 100 nautical miles about the centers and at levels varying from 700 mb to 250 mb are compared with the velocity of the respective storm eyes. The relationship found in hurricanes of the 1955–1957 seasons is such as to indicate that the winds near the center of the vortex have predictive value for hurricane movement.

Bruno J. Giletti (Lamont Geological Observatory, Columbia University, Palisades, N.Y.) *Circulation Rates of Near-Surface Atlantic Ocean Waters and the Cosmic-Ray Production of Tritium*—Surface waters in the North and South Atlantic Oceans were analyzed for their tritium (H^3) concentration. The 1953 H^3:H ratio for the North Atlantic surface was 1.0×10^{-18} (eight samples). In 1954 the average increased to 1.8×10^{-18} (eight samples) as a result of thermonuclear tests. In 1956, part of the South Atlantic Surface Water averaged 0.1×10^{-18} (six samples). This shows that the increment of test debris tritium to the Southern Hemisphere was very small. Two samples indicate the influx into the South Atlantic of some tritium debris. This is under further study to establish surface mixing rates between oceans. The major parts of the North Atlantic Central Waters have a H^3:H $< 0.1 \times 10^{-18}$ (that is, a mean 'age' of $>$40 years). The upper portions of the Central Water do yield measurable H^3(H^3:H $= 0.3 \times 10^{-18}$ for three samples). Based on the above surface data it is possible to calculate the influx rate of tritium into the North Atlantic Surface Water and therefore find the cosmic-ray production rate of tritium. The new South Atlantic data require an influx of 1.4 H^3 atoms/cm^2 sec into the North Atlantic. Taking residence times for tritium in the atmosphere into account, calculations yield a total production rate of 1.8 H^3 atoms/cm^2 sec.

Thomas A. Gleeson (Department of Meteorology, Florida State University, Tallahassee, Fla.) *Probability of Observing Specific Phenomena from Network Stations*—The probability that an atmospheric feature of a given size will be observed in a region with a network of stations randomly distributed relative to the feature is shown to be a function of the feature size and the density of the network. The latter is defined as the number of stations divided by the size of the region. The function is developed to give the probability of observing several features simultaneously in a network of stations with varying observational capabilities. Applications to network design, climatology, and prediction are discussed, and effects of a variation in network density are considered.

T. Gold and D. H. Menzel (Harvard College Observatory, Cambridge, Mass.) *A New Method of Obtaining Seismic Information*—The artificial generation of usable seismic signals has so far been achieved only with explosions. The present proposal is to use an oscillatory signal transmitted into the ground by a special mechanical generator, and to receive the signal at one or many places with a receiver using a new phase-sensitive integrating technique. The great discrimination against random disturbances and noise enables this technique to achieve a sensitivity equivalent to an increase by a factor of several thousand in the transmitting power. Variations of the reception pattern with frequency give significant information about the sub-surface structure. Feasible transmitter designs indicate the possibility of attaining very great ranges. Measurements of attenuation, seismic path-length, and other characteristics can be carried out. A large installation working on this principle may send a signal to the antipodes.

S. S. Goldich, A. O. Nier, and H. Baadsgaard (University of Minnesota, Minneapolis, Minn.) *Three-fold Division of Precambrian in the Lake Superior Region*—K-A dating supports the three-fold division of the Precambrian of Minnesota and adjacent areas. The three divisions from dating of major orogenies and unconformities are early Precambrian (older than 2.5 b y), Middle Precambrian (2.5–1.6 b y), and late Precambrian (1.6–0.5 b y). The major orogeny at the end of early Precambrian time is dated by numerous samples from Ontario, northern Minnesota, and the Minnesota River Valley. A second major folding marks the close of the Middle Precambrian and involved Animikian sediments in Minnesota, Wisconsin, and Michigan. Geologic time since 1.6 b y is assigned to the late Precambrian. Keweenawan lavas and the Duluth gabbro complex are assigned to the Middle Keweenawan. The main gabbro intrusion is dated at 1.1 b y, but folding and metamorphism of the extent developed at this time in the Grenville Province still remain to be recognized in the Lake Superior region.

S. S. Goldich, A. O. Nier, H. W. Krueger, and J. H. Hoffman (University of Minnesota, Minneapolis, Minn.) *K-A Dating of Precambrian Iron Formations*—K-A dating indicates that iron formations were involved in each of the major orogenies of the Canadian Shield. Soudan-type of iron formations in Minnesota and Ontario were folded in a 2.7–2.5 b y orogeny. Mesabi-type of iron formations in Minnesota, Wisconsin, and Michigan were involved in folding at 1.8–1.6 b y, and iron formations in Quebec (Ungava-type) were folded in the 1.2–1.0 b y or Grenville orogeny as indicated by samples from the Jeanine Lake and Mt. Reed deposits. Sericite samples from the Soudan Mine, Minnesota, date two periods of mineralization. The older sericite (2.5 b y) is related to folding at the end of early Precambrian time. The younger sericite (1.7 b y) indicates that the deposits were reopened at the time of the Middle Precambrian (post-Animikian) orogeny. Geologic data indicate that iron formations probably were deposited at different times within each of the main divisions of the Precambrian. Further studies are needed.

D. T. Griggs, H. C. Heard (University of California, Los Angeles 24, Calif.), F. J. Turner (University of California, Berkeley 4, Calif.), and M. S. Paterson (Australian National University, Canberra, Australia) *Recrystallization in Calcite Crystals and Aggregates*—Yule marble highly strained at 600°C, 5 kb confining pressure, exhibits partial syntectonic recrystallization. The new crystals are highly oriented, with the c axis parallel to the maximum compressive stress, consistent with G. J. F. MacDonald's revised thermodynamic theory. When strained at 700° and 800°C, 5 kb, the recrystallization is markedly less evident. Annealing experiments similar to those of Buerger and Washken were performed at high pressure. The sample is first strained at room temperature under a high confining pressure. The shear stress is then removed and the sample is heated at pressure. Development of a completely recrystallized granoblastic texture with polygonal grain outlines will be illustrated. Porphyroblastic texture will also be shown. The critical temperature for annealing recrystallization of yule marble strained 20 pct at 5 kb is about 500°C. The recrystallized grains in annealed samples are less well oriented than the unrecrystallized fabric. Single crystals of calcite exhibit annealing recrystallization when deformed by either twinning or translation. The recrystallized segments of these grains are commonly oriented with the c axis inclined 25–30° to that of the host. Internally rotated e lamellae and r cleavages frequently act as barriers to new growth and so tend to form boundaries of new crystals. Recrystallization of calcite is similar in every way yet explored to recrystallization of metals. Water and CO_2 do not affect the process in our experience to date.

Irving I. Gringorton (Atmospheric Analysis Laboratory, Geophysics Research Directorate, Air Force Cambridge Research Center, Boston, Mass.) *Equivalent Tailwind Errors of Forecast and Inflight Observation*—In the daily routine of transoceanic flying figures are collected which yield forecast wind factors and observed wind factors from which it is possible to obtain a partial, but adequate, separation of errors. The analysis can provide useful information for the evaluation of the wind forecasts. Coupled with this evaluation a technique is presented for the verification of upper-air prognostic charts.

Donald W. Groff (Department of Geology' Allegheny College, Meadville, Pa.) *A Graphic Approach to Meaningful Radiometry*—A reasonably precise rapid counting technique permitting variable sample weights has been developed. With the use of a nomogram the results may be translated to a common scale giving per cent equivalent uranium. Fifteen samples of known 'uranium equivalent' were exposed beneath a Geiger tube and the results plotted; counts per minute vs sample weights. The graphed curves appear a family of parabolas. Log-log plots indicate a linear relationship with an average slope of +0.4. The maximum standard error of estimate for any individual regression was +0.3 unit and the total correlation coefficient was found to be 0.79.

H. P. Guy (Quality of Water Branch, Water Resources Division, U.S. Geological Survey, Washington 25, D.C.) *A Method for Determining Trend of Suspended-Sediment Discharge in Streams*—The trend of discharge of suspended sediment by streams is evaluated by a graphical method, using measured factors for a storm, including rainfall intensity, quantity and rate of runoff, and season. The method is illustrated by using sediment discharge, water discharge, and precipitation data for the Brandywine Creek at Wilmington, Del., during the period 1947 to 1955. Runoff and sediment data for 123 storm periods representing 89 pct of the total sediment discharge and 19 pct of the total water discharge were used in the analysis. A 38 pct reduction in sediment yield occurred from the first half to the last half of the nine-year period. The relative significance of the trend is shown by a rank-correlation method, and for these data the downward trend is highly significant.

William H. Haggard (Office of Climatology, U.S. Weather Bureau, Washington, D.C.) *The Birthplace of North Atlantic Tropical Storms*—Seventy-one years of North Atlantic tropical storms and hurricanes have been investigated in the Office of Climatology of the U.S. Weather Bureau. The reconstructed storm-track charts were used to investigate the birthplace of North Atlantic tropical storms. The results are discussed in the light of the inadequacies of the observing net. Examples are given of storms whose origins have been especially investigated. Suggestions are offered for improvement of methods for earlier storm detection.

John Handin (Shell Development Co., Houston 25, Texas) *Effects of Temperature on the Strengths of Some Sedimentary Rocks*—Jacketed dry specimens of anhydrite, two dolomite rocks, three limestones, two sandstones, shale, siltstone, and slate, as well as halite crystals, have been tested in triaxial compression at a strain rate of one per cent per minute under confining pressures of 0–2000 bars and at temperatures of 24–300°C. The experimental conditions simulate depths to 30,000 feet. Heating under a given confining pressure can reduce the ultimate strength by lowering the yield stress or decreasing strain-hardening or both. An increase of temperature enhances ductility in all but one dolomite, the shale, and the siltstone. In these a reduction of ductility results in a lowered ultimate strength. Heating can increase strength by enhancing ductility in work-hardening materials, provided that the yield stress is not too greatly decreased. For all materials tested, except the halite, the ultimate strength at any simulated depth exceeds the crushing strength at atmospheric conditions.

G. E. Harbeck and G. E. Koberg (Water Resources Division, U.S. Geological Survey, Denver, Colo.) *A Method of Evaluating Effects of a Monomolecular Film in Suppressing Reservoir Evaporation*—Evaporation from a water surface may be reduced by the application of a monomolecular film. Errors may be introduced in the computed savings if pan measurements are used. Experiments show that evaporation pan coefficients vary with the season, and the coefficients cannot be evaluated accurately. A more reliable measure of the evaporation reduction is obtained by the solution of simultaneous equations based upon energy budget and mass transfer theory. The rise in water surface temperature caused by application of the film can be computed.

HARRY F. HAWKINS (National Hurricane Research Project, U.S. Weather Bureau, West Palm Beach, Fla.) *Hurricane Winds at Flight Levels Related to Low-Level Wind Data*—Flight data collected at the National Hurricane Research Project is supplemented where practical by other reports to afford an empirical relationship enabling the forecaster to estimate the distribution of winds near the surface in hurricanes when given only flight level reports from the 700-mb or higher levels. Stage of growth of the hurricane, general intensity of circulation, and sector of the storm are considered where possible in treating the vertical wind profile.

HUGH C. HEARD (Institute of Geophysics, University of California, Los Angeles 24, Calif.) *The Brittle to Ductile Transition in Solenhofen Limestone as a Function of Temperature, Confining Pressure, and Interstitial Fluid Pressure*—One hundred and fifteen triaxial compression and extension experiments have been performed on the mechanically isotropic homogeneous Solenhofen limestone to determine the transition from brittle fracture to ductile flow as a function of temperature, confining pressure, and interstitial fluid pressure. Temperatures and pressures range from 25°–700°C and from 1–7500 atmospheres; interstitial fluids include water and carbon dioxide. Strain rates remained constant at 10^{-4}/second. Transitional behavior is arbitrarily defined as that point at which three to five per cent strain may be induced without notable loss in cohesion. In dry extension tests, the confining pressure required to induce transitional behavior decreases from 7300 atmospheres at 25°C to about 700 atmospheres at 700°C. In dry compression tests, the pressure required for the transition is 1000 atmospheres at 25°C, decreasing to one atmosphere at 480°C. For transitional behavior in compression tests with interstitial fluids, the difference between confining pressure and interstitial pressure decreased almost exponentially with increasing confining pressure from 1000 atmospheres at 25°C and 850 atmospheres at 150°C to nearly zero at 5000 atmospheres. Sample stress-strain data are presented and compared for a wide range of test conditions. From plots relating transition pressure and transition stress to temperature, maximum and minimum principal stresses and mean stress are derived and reported as a function of temperature. None of the various theories of strength examined were able to correlate results in compression and extension. The Mohr theory was able to predict shear fracture angles at the brittle-ductile transition within 0°–6° for dry compression and 3°–10° for extension at temperatures ranging from 25°–400°C. Fracture angles (to the least principal stress axis) were found to increase with temperature in all cases.

W. A. HEISKANEN AND U. A. UOTILA (Ohio State University, Columbus, Ohio) *On the Accuracy of the Gravimetric N, ξ, and η*—The determination of the vertical deflection components ξ and η and of the undulation N of the geoid is the most important geodetic problem of this decade. When we know N, ξ, and η, we know also the detailed shape of the geoid and its distance from the reference ellipsoid, and we can convert the existing geodetic systems, also across the oceans, to the world geodetic system. Most effectively N, ξ, and η can be determined by the gravimetric method. The authors discuss the following problems: what kind of gravity field is required to get the highest possible accuracy; for what areas the additional gravity observations are mostly needed; what accuracy can be obtained on basis of the existing gravity material; how we can best choose the computation points; how to estimate the gravity anomalies for the unsurveyed areas; what accuracy can we expect in converting the geodetic systems across the oceans; and what accuracy has been, in fact, obtained in the studies of the Columbus group.

HOMER W. HISER (Marine Laboratory, University of Miami, Coral Gables, Fla.) *Anomalous Radar Propagation in South Florida*—Data are presented which indicate that the amount of anomalous propagation observed under given atmospheric conditions is partially a function of radar wave length. Case studies of rapid time variations and marked areal differences in the distribution of anomalous propagation are also presented.

WALTER H. HOECKER, JR. (Office of Meteorological Research, U.S. Weather Bureau, Washington, D.C.) *Comparison of Dimensional and Time-Trend Characteristics of Some Tornadoes and Waterspouts*—Utilizing scale serial photographs of tornadoes, the size and shape trends of several tornadoes (1955–1957) are presented. These are compared to other measurements of tornadoes and waterspouts which occurred between the years of 1896 and 1955. Relationships have been found between width and height of those tornadoes where serial photographs are available and the findings are summarized.

JOHN H. HOFFMAN AND ALFRED O. NIER (University of Minnesota, Minneapolis 14, Minn.) *Cosmogenic Helium Distribution in Iron Meteorites*—Among the evaporation products formed when cosmic rays interact with the nuclei of matter, for example, iron, are He^3 and He^4. The quantity formed of both these isotopes should be a function of their position in a large meteorite mass. A mass spectrometer investigation of the He^3 and He^4 contents in cross sections of the half-ton iron meteorites Carbo and Grant shows a monotonic decrease toward the interior. Whereas the He^3/He^4 ratio in Carbo is approximately constant at 0.24 throughout the meteorite, it decreases monotonically from 0.30 to 0.26 between the surface and center of Grant. Contours of constant He^3 concentrations suggest that Carbo was split at a time recent compared with that required for cosmic rays to generate the He^3 found. The results are compared with computations assuming an omnidirectional cosmic-ray flux interacting with regular-shaped bodies of various sizes.

Marvin D. Hoover (U.S. Forest Service, Rocky Mountain Forest and Range Experiment Station, Fort Collins, Colo.) *Vegetation and Land-Use Effects*—The role of forest and range vegetation in determining streamflow and soil stability is discussed. The limits to possible effects of plant cover changes as controlled by climate, soils, and other factors are considered. Present knowledge is appraised, additional research needs indicated, and suggestions made for future investigations. It is now evident that in certain areas quantity of streamflow is related to plant cover, although it is uncertain how widely results can be applied because of incomplete knowledge. Energy-balance method and other contributions of physicists are helpful. Difficulty in direct measurements may lead to dependence on misleading assumptions. More attention must be given to biological aspects and to differences in water use between plant species. Physical, chemical, and bacteriological quality of water are of concern and deserve greater emphasis in future studies of land-use effects. There are still many questions concerning most efficient plants and management measures to reduce sheet and gully erosion, as well as the relation between plant cover and landslides and other mass movements.

Charles L. Hosler (Pennsylvania State University, University Park, Pa.) *The Role of Dilute Solutions in Nucleating the Ice Phase*—A number of experiments are now complete which demonstrate that a number of soluble salts in extremely small concentrations have a profound effect on the freezing temperature of water. These experiments will be discussed and compared. The conclusion is reached that ions in solution provide an additional manner in which the freezing temperature of water can be elevated.

Floyd W. Hough (2412 N. Columbus St., Arlington 7, Va.) *The Role of the Geodesist*—The contribution of geodesy to the scientific progress of the world is not too apparent to the layman or, perhaps, even to other branches of the geophysical sciences. An attempt is made in this paper to present a portion of the impact of the geodesist upon the civilization of the planet during a historical period of more than two thousand years with a brief preview of its essentialness in the new age.

L. F. Hubert (Office of Meteorological Research, U.S. Weather Bureau, Washington, D.C.) *Distribution of Surface Friction in Hurricanes*—Terms of the horizontal equations of motion are evaluated from the surface data of three hurricanes that entered our southeastern coast, to investigate the magnitude and orientation of the friction vector at anemometer level, and to compare it with non-hurricane situations. While the magnitude of friction increased toward the hurricane center, it is demonstrated that it is not a simple function of wind speed. Furthermore, the component of friction normal to the anemometer wind direction is nearly always significant and in many cases exceeds the tangential component. The implication of these results are mentioned from the viewpoint of the classical definition of wind stress and its variation with height.

F. A. Huff and J. C. Neill (Illinois State Water Survey, Urbana, Ill.) *Application of Several Statistical Methods to Rainfall Frequency Analysis*—Several methods of frequency analysis were investigated using annual and seasonal maxima for 1- to 10-day storm periods in Illinois. Analysis was based upon data from 39 stations for a 40-year period. Several commonly used statistical distributions, such as the Gumbel and log probability laws, were compared for goodness of fit. Differences obtained in data fitting by application of the methods of moments and least squares were investigated. Consideration was given to both individual station analysis and to grouping of station data within meteorologically homogeneous areas for derivation of the Illinois frequency relations. Final relations were determined using the areal approach in which the state was divided into four sections having similar storm characteristics. Confidence limit computations were made to define the range of variability about the areal mean frequency curves.

C. E. Jacob (Box 347, Northridge, Calif.) *Salt-Water Encroachment in Inclined Confined Aquifers of Nonuniform Thickness*—This is a generalization of an earlier paper on uniform horizontal aquifers. By the method of Dupuit, simultaneous partial differential equations are obtained for the salt-water flow and the fresh-water flow. Integrations are possible in certain cases of steady flow, both opposed and parallel. Nonsteady states are treated by graphical integration between successive steady states or uniformly varying states. Simultaneous finite-difference equations are set up for numerical integration or solution by electronic analog. The long-term time characteristics of such systems are considered, also the lagging of the encroachment behind the lowering of head landward from the salt water lens. Tidal phenomena, diffusion, and rinsing are also discussed.

W. S. Jardetzky (Lamont Geological Observatory, Columbia University, Palisades, N.Y.) *On a Direct Representation of a Disturbance in an Elastic Medium*—The expressions for displacements derived by Ostrogradsky (1831) directly from the equations of motion are presented in a slightly generalized form. This solution has a very important form for the interpretation of propagation of a disturbance in an elastic medium from a limited region in the latter. It appears that the disturbance at every point of an unlimited medium results from the superposition of effects propagating from that region with velocities ranging from the velocity of compressional waves to that of the shear waves, in accordance with a similar conclusion reached by Love.

R. Jastrow and I. Harris (U. S. Naval Research Laboratory, Washington, D. C.) *Upper Atmosphere Properties from Minitrack Observations on 1957 $\alpha 2$*—The analysis of Minitrack data on the first U.S.S.R. satellite, 1957 $\alpha 2$, provides information on the density and temperature of the atmosphere above the perigee altitude of 232 km. The combination of the $\alpha 2$ data with recently obtained rocket data at altitudes below 200 km leads to a relatively unambiguous determination of density up to 400 km. We find that at 275 km the density is 1.4×10^{-13} g/cm^3 or 13 times the ARDC density, with an uncertainty of 30 pct; at 400 km the density is 2×10^{-14} g/cm^3 or 40 times the ARDC density, with an uncertainty of a factor of 2; and at 800 km the density is 10^{-16} g/cm^3 or 100 times ARDC density, with an uncertainty of a factor of 5. Upper atmosphere temperatures appear to be higher than those in earlier models. At 250 km the temperature is found to be 1600° ± 400° K, as compared with 900° K in the ARDC model. The lifetimes for existing satellites, as determined by our model, are as follows: 1958 α, minimum one year, probable value two years; 1958 β, 80 to 400 years; 1958 γ, minimum 70 days, probable value 140 days. The minimum values quoted for 1958 α and 1958 γ are based on the assumption of a 90° angle of attack at perigee. The range given for the lifetime of 1958 β corresponds to the probable error in density of our model at the perigee altitude of that satellite.

K. R. Johannessen (Directorate of Scientific Services, Air Weather Service, Andrews Air Force Base, Washington, D.C.) *Some Studies of 'Weather' as an Initial Value Problem*—The effects of inadequate definition of the initial values may be studied systematically when a mathematical prediction model exists for the problem. Such effects have been studied by Thompson, Best, and others for the problem of large-scale flow prediction. Successful predictions of 'weather'; that is, fog, clouds, precipitation, visibility, etc., require ideally an extremely complex set of initial values, among them the parameters currently used in large-scale predictions of flow. In this connection forecasters are often faced with the question: What is the minimum amount of data which will permit operationally useful forecasts of 'weather'? This paper reports on results of applying varying types and amounts of data towards the problem of predicting cloud at mid-tropospheric levels, including those characterizing the large-scale flow.

R. K. C. Johns (Laboratory for Electronics, Inc., Boston 14, Mass.) *Adjustment of Conditioned Observations with Unknowns*—A method of adjustment with two kinds of unknowns is developed. Some unknowns are directly observed, the others are indirectly determined from the observations. In the described method fictitious observation equations with corresponding weights are introduced and equivalent normal equations formed. An application for simultaneous determination in geodetic astronomy is given.

C. Y. Johnson, E. B. Meadows, and J. C. Holmes (U. S. Naval Research Laboratory, Washington 25, D. C.) *Ion Composition of the Arctic Ionosphere*—Three Aerobee-Hi rockets identically instrumented with Bennett radio frequency ion mass spectrometers were launched from Fort Churchill, Canada, on November 20, 1956, February 21, 1958, and March 23, 1958; their peak altitudes were 251, 225 and 202 km respectively. The November flight was at night into an overcast which prevented observation of the overhead sky. The February flight was at night and entered an auroral display. The March flight was at noontime. Positive and negative ions were detected on all flights. Masses 32^+ (O_2^+), 30^+ (NO^+), and 16^+ (O^+) AMU were the major positive ions detected. An ion in the region of mass 46^- (NO_2^-) was the negative ion detected. Mass 30^+ (NO^+) is the predominant positive ion at night below 200 km, but during the day is supplanted by 32^+ (O_2^+) below 100 km, and by 16^+ (O^+) above 150 km. Mass 16^+ (O^+) does not appear below 130 km, but becomes the predominant ion above 200 km on all flights. In addition, small amounts of 28^+ (N_2^+), 18^+ (H_2O^+ ?), and 14^+ (N^+) AMU were detected on all flights. An important feature of the February 1958 data is the approximately equal abundance of ions 32^+ (O_2^+), 30^+ (NO^+) and 28^+ (N_2^+) AMU which occurred in the 100–105 km. region of an auroral display.

C. L. Jordan (Florida State University, Tallahassee, Fla.) *The Thermal Structure of the Hurricane Core*—Many aircraft and dropsonde observations have been made in and near the eye of hurricanes in recent years. The dropsonde observations have enabled the preparation of mean eye soundings for hurricanes of various intensities, and the aircraft observations provide information on the horizontal temperature gradients in and near the eye. The three-dimensional temperature distribution in the hurricane core, as derived from these observations, is discussed along with the vertical circulation patterns which have been postulated for this portion of the hurricane.

Donald L. Jorgensen (Forecasts and Synoptic Reports Division, U.S. Weather Bureau, Washington, D.C.) *Predicting Atlantic Coast Hurricanes by Means of Synoptic-Climatological Relationships Using Orthogonal Polynomials*—The Wadsworth-Bryan method of specifying atmospheric circulation patterns is used as a basis for developing a hurricane forecasting procedure. Regression equations have been calculated using persistency and circulation parameters to give 24-hour components of motion for hurricanes threatening the middle and north Atlantic coast areas. The final forecast is expressed in terms of probability areas.

Paul Julian, William R. Larue, and Hans Panofsky (Pennsylvania State University, University Park, Pa.) *Estimation of 100-mb Flow from 500-mb Space Smoothed Charts*—The contour pattern in moderate latitudes at 100-mb resembles 500-mb patterns with the short waves smoothed out. It is shown that space-smoothed 500-mb charts can be used satisfactorily to estimate 100-mb contour patterns and winds. Even in polar regions, changes in the mean flow at 500-mb are shown to be well correlated with changes at 100-mb.

Christian E. Junge (Geophysics Research Directorate, Air Force Cambridge Research Center, Bedford, Mass.) *The Sulfur Budget in the Atmosphere*—On the basis of rainwater analyses data, estimates on the global budget of the sulfur are given. It appears that about 30 pct of the sulfur can be accounted for by human activities. Analyses of ice samples from Greenland back to the year 1915 will be used to check this result. A review of the facts and problems of the sulfur cycle in the atmosphere will close the considerations.

K. Kajiura (Department of Oceanography and Meteorology, A and M College of Texas, College Station, Texas) *Effect of Coriolis Force on Edge Waves: II, Specific Examples of Free and Forced Waves*—The modification of edge waves due to the presence of the Coriolis force is examined in terms of two specific problems. In particular, the dispersion of an initial deformation of the water surface and the forced wave due to a moving atmospheric pressure disturbance are discussed. In both cases, the scale of the disturbance is an important factor and the larger the scale, the larger is the effect of the Coriolis force. In the northern hemisphere the initial deformation of the water surface is split into two free edge waves in which the wave moving to the left facing the coast from the sea side has a larger amplitude than the wave moving to the right. The contribution of the Coriolis force to the edge-wave amplitude for an initial deformation of several hundred kilometers is about 20 pct at the center in the initial stage. In the case of forced waves, the movement of the atmospheric pressure system to the left is more favorable for exciting resurgent edge waves than the movement to the right. The contribution of the Coriolis force is about 10 to 20 pct in the amplitude of the edge waves if the atmospheric disturbance of several hundred kilometers in diameter moves to the left with a speed of about 20 to 30 knots.

Akira Kasahara (Department of Meteorology, University of Chicago, Chicago, Ill.) *A Comparison between Geostrophic and Quasi-Nongeostrophic Numerical Forecasts of Hurricane Movement with the Steering Model*—The steering flow of a hurricane is obtained by eliminating the vortex field from the total flow field. The evolution of the steering flow is predicted by solving the barotropic nondivergent vorticity equation. Based upon the steering-flow prediction, a forecast of the hurricane movement is obtained with the use of an equation which provides for interaction between the hurricane and the steering flow. In the geostrophic steering model, the geostrophic-wind assumption is used for convenience in solving the vorticity equation. In the quasi-neogeostrophic steering model, this assumption is discarded and the stream function governed by the 'balance equation' is adopted as a parameter for solving the vorticity equation.

With the above two models, a total of 94 predictions of the 24-hour and 48-hour movement of hurricanes Diane, Connie (August 1955), and Betsy (August 1956) at the 500- and 700-mb levels were prepared by the use of an electronic computer. A detailed discussion of the above results is presented. Generally speaking, the performance of the quasi-nongeostrophic steering model indicates a tendency to improve the accuracy of the hurricane movement forecast in comparison with that of the geostrophic steering model.

W. M. Kaula (Army Map Service, Washington 25, D.C.) *A Statistical and Harmonic Analysis of Gravity*—Stochastic process methods have been adapted to analyze gravity using spherical harmonics in place of the customary Fourier functions. Transition matrices and autocovariances of free air anomalies were computed from a world sample of 749 observations (of average spacing 500 km), eight regional samples (100 km), and nine local samples (15 km). These samples were divided into various sub-samples in order to obtain either balance with respect to regional topography or smoothing out of local topography.

From the autocovariances can be obtained the variance, or power, of each harmonic degree of gravity. These variances are usable in turn for: (1) the variances and covariances of geoid heights and deflections of the vertical; (2) conditions on the magnitudes of the degrees in direct harmonic analysis of gravity; (3) errors of representation of gravity observations; and (4) the variances and autocovariances of the gravitational field at any altitude, from which a statistical estimate can be made of satellite perturbations.

Gilbert D. Kinzer and W. E. Cobb (Office of Physical Research, U.S. Weather Bureau, Washington, D.C.) *Analysis of the Growth and Collection Efficiency of Cloud Droplets*—Experimental collection efficiencies obtained from the data agree within limits of experimental error with those calculated from a theory that is developed from intuitive physical arguments which are based on a superimposed random motion observed in the fall of droplets in the supporting cloud. The theory implies that a small-scale eddy diffusion transfers smaller droplets from the parent cloud to the growing droplet. The coefficient of droplet transport calculated from the theory agrees well with one evaluated experimentally.

Carl Kisslinger (St. Louis University, St. Louis, Mo.) *Observations of the Development of the Surface Wave Pattern in the Vicinity of Small Explosions*—Displacements at the surface of a relatively simple layered system have been recorded at distances from 25 to 700 ft from a number of small explosions by means of three-component mechanical-optical seismographs. The characteristics of the surface waves generated have been determined as the first step in a further study of the factors governing these characteristics. Two seismic models are represented by the field conditions. Excellent reproducibility of recorded motion was obtained from repeated shots under similar circumstances. From a study of the particle motion diagrams in the vertical-longitudinal plane, distinct wave types, well separated at the larger distances, can be followed back to their rudimentary form at the smaller distances. The Rayleigh wave in both models is not strongly dispersed, but consists of a single large ellipse, followed by a brief train of shorter period waves of much smaller amplitude. This train does not lengthen appreciably with distance. In one model, the Rayleigh wave is preceded by well-defined direct elliptic motion of shorter period. This motion develops into two successive trains, in each of which the period decreases slightly with time. Differences in the complexity of the recorded motion in the two models is noted.

Melvin H. Kleen and William H. Sammons (Central Technical Unit, Soil Conservation Service, Beltsville, Maryland) *Agricultural Watershed Influences on Runoff Potential*—Annual and seasonal precipitation and runoff data for selected agricultural watersheds in the United States were analyzed statistically for relationships pertinent to the watershed program of the Soil Conservation Service. Records in the Monthly

Precipitation and Runoff for Small Agricultural Watersheds in the United States as published by U. S. Department of Agriculture, Agricultural Research Service, Soil and Water Conservation Research Branch, were considered. A water year, growing season, and dormant season for the selected watershed were based on Figure 90, Average Dates of Last Killing Frost in Spring, and Figure 107, Average Dates of First Killing Frost in Fall, in the section on *Climate-Frost and the Growing Season* of the *Atlas of Americn Agriculture* (1936). Watersheds were variable in area, climate, slopes, soils, flow character, cover conditions, etc. The study was centered about the relationship $(P - Q)/S = Q/P$, where P is the precipitation in inches, Q is the runoff in inches, and S is the maximum potential difference between P and Q for the period, in inches. $(P - Q)/S$ is visualized as the ratio of actual to potential difference between P and Q, and Q/P is visualized as the ratio of actual to potential runoff. Under this hypothesis, the data were studied and recommendations and conclusions presented.

L. Knopoff, J. F. Gilbert, and W. L. Pilant (University of California, Los Angeles, Calif.) *Pulse Propagation in a Medium with a Single Layer*—The generation of Love SH-waves has already been studied. In a similar way the propagation of *P-SV* motions in a layered medium can be represented as the sum of contributions from an infinite set of images of the source taken in the two boundaries. The train of Rayleigh waves is seen to lengthen as the epicentral distance increases. The other important pulse groups are the refracted P and S events; each of these lengthens with increase in epicentral distance. A seismic model has been set up to demonstrate these features; the details predicted above are observed with high fidelity. The long duration and the modulation envelopes of the refracted P and S events are features not heretofore anticipated, but whose existence have since been verified theoretically. A new experimental technique for directly determining the group velocity in layered structures is presented and the results for the seismic model with one surface layer agree with the theoretical values.

Leon Knopoff (University of California, Los Angeles, Calif.) and Gordon J. F. MacDonald (Massachusetts Institute of Technology, Cambridge, Mass.) *The Magnetic Field and the Central Core of the Earth*—The suggestion that the inner core of the Earth is liquid and is the seat of a strong magnetic field is examined. Contrary to expectations of a magnetohydrodynamic rigidity for the inner core, a liquid inner core with a strong magnetic field should not transmit shear waves. The absence of the phase *PKJKP* in seismic records is favorable to the hypothesis of a strong magnetic field in a liquid inner core. If the jump in P-wave velocity at the inner core boundary is due to a magnetic field, the strength of the field must be of the order of 5×10^6 gauss whether the field geometry is toroidal or random. A strong toroidal field leads to a seismic ellipticity of the inner core. No such ellipticity is observed. Hence if the field in the inner core is toroidal, it must be less than 5×10^5 gauss. A random field does not lead to an ellipticity and the limit on the magnitude of a random field is determined from seismic velocities. A difference in iron-nickel to silicon ratio between the outer and inner core is suggested as leading to a discontinuity in conductivity whereby a strong field could be stored in the inner core. Consequences of the liquid inner core model include (1) a central temperature in excess of 4000°K and (2) a magnetic time constant of about 5000 years.

Adam Kochanski (Headquarters, Air Weather Service, Andrews Air Force Base, Washington, D.C.) *Route Winds for Flights at 300 and 200 mb*—Commercial jet airliners operating near the level of maximum wind will create a new problem. Critical values in fuel reserve and in errors of wind forecasts will have to be considered on a routine, day-to-day basis. This paper discusses our present capability of forecasting route winds at 300 and 200 mb. Vector errors and tail-component errors of 36-hour and 48-hour route winds were evaluated using prognostic and verifying charts. Estimates of errors of 12-hour and 24-hour forecasts are also given. In general, the errors decrease steadily with increasing route length and the rate of this decrease seems to be nearly constant for most of the middle latitudes and for 24-, 36-, and 48-hour forecasts.

J. Laurence Kulp and L. E. Long (Lamont Geological Observatory, Columbia University, Palisades, N. Y.) *Chronology of Major Metamorphic Events in Southeastern United States*—Absolute age measurements by the potassium-argon, rubidium-strontium, and uranium-lead methods on rocks from New York to Georgia suggest that the major metamorphic event occurred about 360 m y ago. This orogeny produced the homogeneous granites of the Piedmont (previously called '*Carboniferous*') and either formed or recrystallized the gneisses and schists. Thus, rocks that may be Grenville in age, for example, Fordham gneiss, Baltimore gneiss, and Carolina gneiss and schist give approximately the same apparent age by the potassium-argon method as the rocks that may be post-Cambrian, for example, Inwood marble, Gaffney marble, Wissahickon schist, and Manhattan schist. In western North Carolina a transition of apparent ages from 360 to 800 m y occurs in the same rock unit sharing the margin of the 360 m y event. In the southeastern Piedmont of Georgia there is evidence for a younger event occurring around 260 m y ago.

M. Landisman and Y. Sato (Lamont Geological Observatory, Palisades, N. Y.) *Shear Wave Velocities in the Upper Mantle*—A period equation has been developed for Love waves in models having two homogeneous layers over a half space with linear gradients in both density and shear modulus. The dispersion for various theoretical models of this class was compared with observations of Love wave group velocity for periods from 20 to 300 sec. Shear wave travel times for spherical Earth models having these velocity structures were compared with observations from earthquakes. It is concluded that a knowledge of the exact structure of the crust is not necessary for an investigation of the shear velocity in the upper mantle, while crustal investigations do require some knowledge of mantle structure. The only shear velocity structures which are concordant with observations of surface wave dispersion and body wave travel times are those containing a low velocity layer in the region from roughly 100 to 200 km below the Earth's surface. Further studies to define the structure of this low velocity channel are in progress.

W. B. Langbein (U.S. Geological Survey, Washington 25, D.C.) *Basic Hydrologic Data for Upstream Engineering and Land Management*—Land use is water use, and erosion control means water control. These are the basic precepts of upstream engineering and land management. Hydrologic data therefore are at the core of any plans for these purposes. But far more detailed knowledge is needed than now exists. The extensive programs for upstream watershed practice and land management are guided by sound but generalized data. The available information is not nearly detailed enough to provide answers to the almost infinite variety of field conditions which are encountered.

N. E. Laseur (Department of Meteorology, Florida State University, Tallahassee, Fla.) *Detailed Low-Level Wind and Pressure Data from Hurricane Edith, 1955*—Special aircraft reconnaissance flights on four consecutive days, August 27–30, 1955, into Hurricane Edith, yield data which permit quite detailed analysis of low-level (1000 to 1500 ft) wind and pressure fields. A description of the micro-structure revealed by these analyses will be presented together with a discussion of relationships with cloud and weather patterns.

A. W. Lawson and John C. Jamieson (University of Chicago, Chicago 37, Ill.) *Energy Transfer in the Earth's Mantle*—Several processes of energy transfer in the Earth's mantle are examined: (1) grey radiation, (2) ambipolar diffusion of electron-hole pairs, (3) exciton transfer, and others. Using Rikitake's values of the electrical conductivity, corrected for the infrequency dependence and the refractive index variation with depth, the values for the radiative contribution to the heat flow were found to be appreciably larger than those estimated by Clark. Estimation of the electronic processes indicate that they may be an important component of the heat flow in the lower parts of the mantle. All processes considered tend to increase the heat conductivity of the mantle and thereby presumably lower the estimate of the temperature at the base of the mantle.

Dale F. Leipper (Department of Oceanography and Meteorology, A and M College of Texas, College Station, Texas) *The Impact on Oceanography of the NAS Meteorology Report*—The Committee on Meteorology of the National Academy of Sciences-National Research Council submitted an interim report in January 1958 on Research and Education in Meteorology. Although this report concerns the history, present status, and future of meteorology, it carries with it considerable implications for the field of oceanography. These will be discussed.

Dale F. Leipper (Department of Oceanography and Meteorology, A and M College of Texas, College Station, Texas) *Staff and New Facilities in Oceanography at Texas A and M*—The Department of Oceanography and Meteorology, A and M College of Texas, has obtained a building on the beach at Galveston for the purpose of enlarging its marine laboratory there. K. M. Rae has been named Director of Marine Laboratory Programs with offices in College Station, and Albert Collier is Chief Scientist of the Galveston Marine Laboratory. The Texas A and M Research Foundation has obtained the 126-ft *Hidalgo*, former PCS, and the 56-ft motor sailer *Elena* for use in oceanographic research. The former is participating in the program for the IGY. J. R. Lumby has been named associate director of the IGY Oceanographic Archive. On the campus, the digital computer laboratory and Nuclear Science Centers are developing rapidly.

Edward N. Lorenz (Department of Meteorology, Massachusetts Institute of Technology, Cambridge, Mass.) *Non-Linear versus Linear Objective Weather Predictions*—A prediction formula is called linear if an observable predictand is expressed as a linear combination of present and past observable predictors. Most of the recently established empirical prediction formulas are linear. An artificial series of 'weather maps' is constructed in which the best predictions of future displacements of pressure systems are linear functions of past displacements. The corresponding formulas for future pressures in terms of present and past pressures are nonlinear. The reduction of variance obtained in predicting pressure by these nonlinear formulas cannot be duplicated by the best linear approximations to them. This situation still prevails when 'observational' errors are introduced into the series. When the best linear approximations to the displacement method of forecasting are applied to actual weather data, the formulas obtained are nearly the same as those previously established by standard linear regression methods. It is concluded that only slight future improvement in short-range prediction of pressure can be expected from linear formulas, but that nonlinear formulas may yield great improvement.

J. R. Lumby (A and M College of Texas, College Station, Texas) *Present Status of the Data Center (A) for Oceanography*—Oceanographic data have been flowing fairly steadily into the center at the A and M College of Texas. Cruise data have been received from Brazil, Canada, France, Japan, The Netherlands, South Africa, the United States, and the U.S.S.R. Sea-level data have been received from Mexico, the United States, and the U.S.S.R. The records vary considerably in both form and content, especially as regards information subsidiary to the main data.

Iver A. Lund, Eugene J. Aubert, and Albert Thomasell, Jr. (Atmospheric Analysis Laboratory, Geophysics Research Directorate, Air Force Cambridge Research Center, Boston, Mass.) *Some Six-Hour Predictions Prepared by Statistical Methods*—Predictions of pressure, temperature, precipitation, cloudiness, and visibility were prepared using linear regression methods. Factor analysis techniques were employed for the purpose of isolating from a complex of variables a small number of factors which accounted for most of the predictand variation. A screening technique was used to select from the same complex of variables those few variables which when combined linearly provided the 'best' forecast.

Gordon J. F. MacDonald (Massachusetts Institute of Technology, Cambridge, Mass.) and Leon Knopoff (University of California, Los Angeles, Calif.) *The Chemical Composition of the Outer Core*—The average composition of the Earth is assumed to be that of chondritic meteorites. This assumption is consistent with the present rate of heat production in the Earth. An iron-nickel core is consistent with the chondritic model only if the upper mantle is mainly pyroxene, a condition inconsistent with seismic data. If the mantle is assumed to be made up of a 400-km shell of the composition of eclogite underlain by a material of the composition of dunite, the chondritic model requires a core of composition (Fe, Ni)$_{1.6}$Si. From the asymptotic relations in the Thomas-Fermi-Dirac model, the representative atomic number (r.a.n.) of Fe$_{1.6}$Si is 22.8. Bullen's density distribution gives a r.a.n. for the outer core of 22 ± 1. The composition of the core deduced from equation of state arguments is thus consistent with the chondritic model of the Earth. It is suggested that iron-silicide is formed by squeezing oxygen out of Fe$_2$SiO$_4$ at high pressures. The electrical conductivity of Fe$_{1.6}$Si is consistent with the requirements of dynamo theories of the magnetic field.

L. Machta (Office of Meteorological Research, U.S. Weather Bureau, Washington, D.C.) *On the Use of Carbon 14 as a Tool in Meteorology*—Carbon 14 is produced by the action of neutrons on atmospheric nitrogen and may be created either through cosmic-ray action or as a byproduct of nuclear tests. Naturally formed carbon 14, with its 5600 year half-life, is uniformly distributed throughout the atmosphere as carbon dioxide. Differences in the ratio of carbon 14 to stable carbon in CO$_2$ may reflect an increase in stable carbon due to the growth of CO$_2$ from the burning of fossil fuels. It has been suggested that the bulk of the weapon carbon 14 was carried by the rising atomic cloud into the stratosphere. Measurements of its reappearance at the ground yield clues as to the removal locations and times from the stratosphere. Quantitative computations are hampered by a lack of knowledge of the initial stratospheric source strength, CO$_2$ exchange rate with oceans, and utilization by plants.

Royal R. Marshall (Enrico Fermi Institute for Nuclear Studies, University of Chicago, Chicago, Ill.) and David C. Hess (Argonne National Laboratory, Chicago, Ill.) *Lead from Stone Meteorites*—Microgram quantities of lead have been separated from several chondrites by volatilization from graphite crucibles at 1200–1400°C. Mass spectrometric analyses have been made on approximately one microgram amounts using boric acid with tantalum filaments. As compared to the PbS method, this technique of placing the lead on the filament raises the strength of the ion beam for small samples by about an order of magitude. The leads from Holbrook, Beardsley, and Plainview are substantially less radiogenic than modern average crustal lead. The concentrations in these meteorites are a few tenths of a ppm, several times as high as found for Richardton and Forest City, which have no more than about 0.1 ppm. Richardton has considerably more radiogenic component than typical terrestrial lead, but somewhat less than found by Patterson for the Nuevo Laredo meteorite. The same lead-lead age, 4.6×10^9 yr, is deduced from both leads. Ages from the others range to somewhat lower values. The concentrations of lead are 1.5 to 3 times as great as should result from the observed amounts of uranium and thorium. Also, the ratios of thorium to uranium appear to be closer to 3 than to 4. Terrestrial values of this ratio are typically between 3.5 and 4.5.

M. Martinelli, Jr. (U.S. Forest Service, Rocky Mountain Forest and Range Experiment Station, Ft. Collins, Colo.) *Some Hydrologic Features of Alpine Snowfields under Summer Conditions*—Ablation, density and weather factors were measured at selected snowfields in the Front Range of Colorado during the summers of 1955 and 1956. Water equivalent of ablation and moisture exchange between the atmosphere and the snow surface were computed. Weekly ablation varied from 2.8 ft on a southern exposure in late August to 1.1 ft on a northern exposure in mid-September. Ablation averaged 1.92 ft per week for July, August, and the first half of September. Snow density increased during the summers, reaching well over 0.70 during August and then decreasing slowly. For each acre of snow existing on August 1, about 11-½ ac ft of water were released by ablation during July and August. This amounted to 0.19 ac ft of water per day per acre of snow. Sverdrup's equation indicated the net moisture exchange between the atmosphere and the snow averaged less than two per cent of ablation. Proposals are made to sustain stream-flow into the summer by the construction of barriers to drift additional snow and by the application of materials to the snow surface to regulate melt.

John T. McCabe and Thomas D. Potter (Headquarters, Air Weather Service, Directorate of Climatology, Andrews Air Force Base, Washington, D.C.) *A Method for the Construction of Climatological Fallout Patterns*—Given the target location, the climatological period (month or season), the fission yield of the weapon, and a critical radiological dose (or dose-rate), a method of finding the frequency that areas about the target will be affected by radioactive fallout of the critical dose is presented. If the actual effective winds, which distribute the fallout particles, are not available, the assumption of a circular normal distribution of the effective wind is made. This distribution can be obtained by C. E. P. Brooks' method or, if the points are numerous, by a mechanical method described herein.

John F. McClay and Paul F. Fougere (Air Force Cambridge Research Center, Bedford, Mass.) *Mutually Consistent Spherical Harmonic Analysis*—New method derives a single set of coefficients A_n^m, B_n^m, α_n^m, β_n^m in spherical harmonic expansion using component data obtained on an arbitrary discrete grid covering a spherical surface. Applies equally well to main field and to secular variation. Since the basis functions P_n^m, X_n^m, and Y_n^m of Schmidt do not form orthogonal sets over an arbitrary grid, simple linear combination of such basis functions which are orthogonal, are obtained in a simple manner. Having expanded the experimental data in a sufficiently large set of such orthogonal functions, it is then easy to determine, by means of the variance ratio test, which members of this set are really useful in representing the original data. Results are obtained in such a way that not only are best fits to the data obtained but also the derived functions are necessarily mutually consistent.

William T. McGuinness and William L. Donn (Lamont Geological Observatory, Columbia University, Palisades, N. Y.) *The IGY Island Observatories: Atlantic*—Part of the IGY oceanographic program involves instrumentation and data collection at a number of fixed island sites (Island Observatories). A description will be given of the Atlantic (and one Indian Ocean) installations together with a report on the progress of data gathering to date. New instrumentation will be described.

R. P. Meyer, J. S. Steinhart, and G. P. Woollard (Department of Geology, University of Wisconsin, Madison 6, Wisc.) *Seismic Determination of Crustal Structure in the Central Plateau of Mexico*—A series of explosions at Durango, Mexico, were recorded along a line southeast from Durango on the Central Plateau of Mexico. The area is characterized by Bouguer anomalies of about −200 mgal. A study of the geologic structure was made and the crustal section down to the Mohorovicic discontinuity determined. Preliminary results indicate a depth to Moho of about 40 km.

Donald S. Miller and J. Laurence Kulp (Lamont Geological Observatory, Columbia University, Palisades, N. Y.) *New Isotopic Data and the Colorado Uranium Mineralizations.* Isotopic measurements on lead from primary pitchblende and intimately associated galena, as well as isotope dilution analyses of uranium and lead in the pitchblende, restrict the area of speculation concerning the origin of the uranium mineralizations of the Colorado Plateau. (1) Concordant ages at both 50 and 200 m y preclude the hypothesis that all deposition took place at the end of the Mesozoic with the higher apparent ages due to contamination by old (that is ~1.0 b y) radiogenic lead from the basement. (2) Identical lead isotopic composition of the pitchblende and galena from the Divide Mine, show that very recently (that is, since 5 m y ago) either deposition occurred here, and possibly throughout the Plateau, or recrystallization with loss of lead occurred. (3) The high radiogenic lead in the Plateau galenas appears to have been derived from a post-Cambrian source.

	Pct 208	Pct 207	Pct 206
K-174 Pitchblende	92.6	5.70	1.68
P-271 Galena	92.7	5.65	1.63

An hypothesis which appears to account for all of the data requires leaching of uranium and lead from a 120–180 m y old tuffaceous source in the sediments with some random leakage prior to the leaching. Proper conditions of ground water circulation may have occurred at one or more periods from about 100 m y ago to the present. In most cases the uranium and radiogenic lead were redeposited close to their source and incorporated in both galena and pitchblende.

R. A. Minzner (Geophysics Research Directorate, Air Force Cambridge Research Center, Bedford, Mass.) *Atmospheric Density from Recent Rocket and Satellite Measurements*—The ARDC Model Atmosphere was based on esentially all upper atmosphere data available at the time of its preparation. Theoretical considerations determined the higher altitude portions of the model. Recent density data up to 200 km altitude, from rocket-borne gages as well as data deduced from orbits of artificial Earth satellites, greatly extend the altitude range of direct observations. Marked diurnal and seasonal variations in some rocket data suggest that atmospheric density at high altitudes is strongly influenced by solar radiation on the atmosphere below the point of measurement. Satellite data from three independent sources are compared with rocket data and with the ARDC Model. Values of densities inferred from orbits of 1957 $\alpha 1$, 1957 $\alpha 2$, and 1957 β are generally self-consistent, but are markedly higher than rocket data. Five satellite-inferred data points between 200 and 275 km suggest an atmospheric density model with densities about eight times those of the ARDC Model. The apparently higher densities from satellite observations may be due in part to additional drag forces of electrostatic origin. Atmospheric models based on satellite drag data will be useful in predicting satellite lifetime but may not necessarily represent true atmospheric density.

J. Murray Mitchell, Jr. (Office of Climatology, U.S. Weather Bureau, Washington, D.C.) *A New Test for Homogeneity of Historical Temperature Records*—A new method of testing the homogeneity of historical temperature series is described which is tailored to the typical characteristics of climatological stations in the United States (station density, length and continuity of records, station history knowledge, etc.). It minimizes several objections to existing homogeneity tests, and is usually capable of describing with statistical significance a slippage of mean of about 0.5°F or more in the period of record at a station due to an inhomogeneity. The feasibility of a similar test for precipitation data will be considered.

J. Murray Mitchell, Jr. (Office of Climatology, U.S. Weather Bureau, Washington, D.C.) *Effect of Changing Observation Time on Mean Temperature*—A study of hourly temperature data at several stations in the United States is described which reveals the effect of arbitrary changes in observation time on the homogeneity of monthly mean temperatures at climatological stations. Results show that the greatest possible effect varies with place and season between less than ½°F and more than 3°F. An example is given to show to what extent the failure of cooperative observers to document observation time changes typically vitiates evidence of secular trends. Evening observations are concluded to be more homogeneous than morning observations.

Walter H. Munk and Richard Haubrich (University of California, La Jolla, Calif.) *The Polar Tide*—We have obtained the energy spectrum of sea level from mean monthly values at each eleven localities. The average record length at the eleven localities is a century. A peak at one cycle per 14 months is identified as the polar tide caused by the Chandler wobble.

Jerome Namias (Office of Meteorological Research, U.S. Weather Bureau, Washington, D.C.) *Improvements in Extended Forecasting Resulting from Employment on Numerical Methods*—Several months experience with numerical predictions of midtropospheric flow patterns carried on with the help of electronic machines is summarized. Although the machine products must still be modified in obtaining five-day prognoses, they have made the forecast procedure easier, speedier, more physical, and objective. More important the results are encouragingly better than the averages of recent years.

Cecil A. Nanney (U.S. Naval Research Laboratory, Washington 25, D.C.) *A Study of Correlations between Earthquakes and Microseisms*—In August, 1954, an investigation was begun to determine whether any correlation existed between earthquakes and microseisms. The study was based largely on previously published microseism data from a number of widely separated stations. It included over three years of microseism data and about 400 documented earthquakes. Because of the relatively frequent occurrence of earthquakes and the apparent effect of various phenomena on microseisms, the study has utilized statistical procedures of sampling and measuring correlations. The study has disclosed that: (1) The microseism frequency (inverse period) and amplitude were found to increase before the occurrence of many large earthquakes ($M \gtrsim 6\text{-}\frac{1}{2}$) and to decrease after their occurrence; (2) deep earthquakes, though not necessarily large, were found to be associated with a similar behavior of the amplitude of microseisms; (3) the study showed that smaller earthquakes were often associated with local increases of microseism amplitude and frequency; (4) very long-period (>10 sec) microseisms were found to be correlated with deep earthquakes; and (5) there was some indication that the propagation direction of microseisms may be associated with the location of significant earthquakes. The findings (1) to (4) are based on a statistical significance level of 0.1.

Chester W. Newton and Harriet R. Newton (Department of Meteorology, University of Chicago, Chicago, Illinois) *Interactions between Large Convective Rainstorms and Environmental Wind Field*—Because of vigorous vertical interchange of horizontal momentum, large convective cloud systems can maintain horizontal velocities appreciably different from that of the ambient air, if the environment is characterized by strong vertical shear. Under jet-stream conditions typical for squall lines, estimated relative motions are of the order 10 m/sec. By analogy with hydrodynamics experiments, it is estimated that non-hydrostatic pressures of 0.5 to 1.0 mb or more may result from such relative motions, near the boundary of the convective system. Variations of the non-hydrostatic pressure with height (because of varying relative motions at different levels) may cause vertical accelerations of the same magnitude as ordinary thermodynamic buoyancy forces. This effect can account for directionally-organized propagation of existing convective systems, which appears to be in good agreement with the observed behavior of large rainstorms as analyzed by use of hourly rainfall amounts.

Walter Nichiporuk and Arthur Chodos (Division of Geological Sciences, California Institute of Technology, Pasadena, Calif.) *Concentration of Vanadium, Chromium, Cobalt, Nickel, and Zinc in the Troilite Phase of Meteorites*—Chemical and x-ray fluorescense methods have been applied to a study of vanadium, chromium, cobalt, nickel, and zinc in troilites from iron and silicate-iron meteorites. The results show that the two kinds of troilite are chemically indistinguishable. Their concentrations of vanadium are low and vary over a narrow range whereas those of cobalt, nickel, and copper vary over a broad range. Different occurrences of troilite within the same meteorite also show considerable variations. The concentrations of zinc appear to be grouped within two distinct regions, one in the proximity of 55 ppm and another above 200 ppm.

Matthew F. Norton and Ross F. Giese, Jr. (Department of Geology, Columbia University, New York 27, N. Y.) *The Role of Wrench Faulting in Orogeny*—The hypothesis that seismic activity in island arcs and fold belts results from basement faulting with a dominant wrench component suggests the corollary that rotation of basement blocks creates some limited basins of sedimentation and elsewhere differentially elevates overlying sediments which then deform under gravitational stresses. The present geology of the Cayman-Puerto Rico trench system appears to illustrate this. Belts of cataclasites, secondary shears, and deformation within taphrogeosynclines in the piedmont of eastern North America define a similar ancient zone which parallels Appalachian folds and is similar in magnitude to the San Andreas system. While rotation along basement wrench faults may initiate sedimentary deformation, its style depends on sediment thickness. Thin shelf sediments are fault-folded and often intensely metamorphosed; geosynclinal sediments undergo alpino-type deformation; and stresses in the already-segmented cratonal basement are relieved by relative movement of blocks with en echelon faulting of overlying sediments.

✓ John A. O'Keefe (U.S. Army Map Service, Washington 25, D.C.) *Report of AGU Committee on Geodetic Applications of Artificial Satellites*—Two meetings of this group have been held. At the first meeting, held in December 1957 on an informal basis, it was recommended that data on regression of the nodes of existing satellites be furnished geodesists as soon as possible. Another recommendation emphasized the need for fresh tracking data, that is, data obtained at comparatively short distance intervals during an orbital revolution.

A second meeting of the Committee was held at Boston, Mass., early in March 1958. The Committee received with great appreciation a report by Luigi G. Jacchia, Smithsonian Institution Astrophysical Observatory, on the basic orbital data for Satellite 1957 Beta during the period November 4, 1957, to February 10, 1958. Major conclusions of this meeting were: (a) In view of the critical need for new studies of satellite orbital theory, experts in celestial mechanics should be relieved from other duties as far as possible and allowed to pursue these studies, and (b) for geodetic purposes, satellite perigees should be as high as possible, consistent with accurate observability. A perigee figure of 1000 km was suggested as a minimum.

Jack Oliver and Maurice Ewing (Lamont Geological Observatory, Columbia University, Palisades, N.Y.) *Short-period Oceanic Surface Waves of the Rayleigh and First Shear Modes*—Waves corresponding to the short-period segment of the Rayleigh mode and to the first shear mode are identified for paths traversing the deep ocean, apparently for the first time. It appears that the reason for the presence of the waves in this case and their conspicuous absence in all other cases is that (a) the shock which excited these waves is the atomic explosion of Operation Wigwam, deep in the Pacific Ocean, (b) earthquake sources are generally too deep to excite short-period waves efficiently. The new data strongly support the normal mode explanation for the dispersion of Rayleigh waves crossing the Pacific Ocean and furnish supporting evidence for the crustal structures previously deduced from surface wave dispersion and from refraction shooting. The unusual characteristics of the body phases and the T phase may probably be explained as well by assuming the source was within the water layer.

Philip M. Orville (Geophysical Laboratory, Carnegie Institution of Washington, Washington, D.C.) *Composition of Unzoned Pegmatites in Southern Black Hills, South Dakota*—Three unzoned pegmatites of contrasting texture and structure in the vicinity of Keystone, South Dakota, have been studied in detail in the field and laboratory. They occur within Precambrian quartz-mica schist country rock and are peripheral to the Precambrian Harney Peak granite. The bulk composition of each pegmatite has been determined and comparison of their chemical compositions shows them to be almost identical. Compositions of the Harney Peak granite have also been determined at two localities and these are very close to the pegmatite compositions. The modal compositions of the pegmatites and the Harney Peak granite are approximately 15 pct microcline, 40 pct albite, 35 pct quartz, and 10 pct muscovite. The nearly identical pegmatite compositions and their close correspondence to the composition of the Harney Peak granite suggest a common source of granitic magma of uniform composition for both the pegmatites and the Harney Peak granite.

Hans A. Panofsky and V. R. K. Rao (Pennsylvania State University, University Park, Pa.) *The Relation between Lagrangian and Eulerian Correlation*—The observations of dispersion of SO_2 in project Prairie Grass are used to determine Lagrangian correlation coefficients. These are compared with simultaneous Eulerian coefficients. Although the Lagrangian coefficients are not well determined by the observations, particularly at daytime, the results are consistent with the hypothesis that Lagrangian and Eulerian correlation functions have the same shape but different time scales. In particular, both show similar diurnal variations. At night, when the coefficients are best determined, the ratio of Lagrangian time scale to Eulerian time scale is of order 3.

H. V. Peterson (U.S. Geological Survey, Denver Federal Center, Denver, Colo.) *Erosion and Sediment Problems on Western Arid Lands*—Erosion on arid lands differs from erosion in humid areas mainly in extent and intensity. Sheet erosion, rilling, and gullying in more humid localities occur in the West, but gullying is by far most serious. In many areas erosion evolves from gully cutting to extensive sheet erosion and rilling, and finally to badland formation. Widespread gullying has resulted from: (1) the prevalence of alluvium-filled valleys susceptible to cutting; (2) aridity, with its characteristic relatively wide range in magnitude and intensity of rainfall and runoff resulting in a precarious balance between protective vegetation and erosion; and (3) distinct changes in land use following settlement. Sediment from gullying, and subsequent development of sheet erosion and rilling deteriorating into badlands, can be measured accurately. Potential sediment from untreated areas can be predicted. Hydraulic action of streamflow transports the sediment through the drainage system, and eventually out of the basin. Attempts at treatment have varied. Earliest efforts were designed to "keep the raindrop where it falls." Later the principle of flood control was stressed. Most recent efforts aim to restore the valley floors through induced aggradation and refilling of the gullied channels.

B. B. Phillips and Gilbert D. Kinzer (Office of Physical Research, U. S. Weather Bureau, Washington, D. C.) *Measurements of the Size and Electrification of Droplets in Cumuliform Clouds*—The size and the free electric charge of more than 6000 individual natural cloud droplets have been measured. The measurements were made at a mountain laboratory in southeastern United States in stratocumulus clouds and in thunderstorm-associated clouds. Stratocumulus clouds with fair-weather electric fields were found to have approximate Gaussian charge distributions symmetric about zero charge. The magnitude and distribution of charge observed on these non-storm clouds approach values described recently by R. Gunn in his theory of aerosol electrification by the diffusion of environmental light ions. Thundercloud droplets were highly electrified and within given cloud volumes the droplets were charged entirely positive, entirely negative, or fractionally positive and negative.

Willard J. Pierson, Jr. (College of Engineering, New York University, New York, N. Y.) *Linear and Non-Linear Problems in Wave Theory for Waves Influenced by Both Gravity and Surface Tension*—Recent results by G. D. Crapper show that the troughs of pure capillary waves point into the water sharply and that the crests are rounded. This is the opposite to the behavior of gravity waves. It is shown that for a wide range of wave frequencies neither the usual gravity wave approximation nor the usual capillary wave approximation is very good. It is also shown that the change-over in appearance takes place at a wave length of 2.44 cm, and that the waves may even be steeper than the /λ value of 0.730 given by Crapper for capillary waves.

Donald J. Portman (Willow Run Labs., University of Michigan, Ypsilanti, Mich.) *Conductivity and Length Relationships in Heat-Flow Transducer Performance*—In recent years many investigators have used thermoelectric heat flow transducers to measure heat conduction in natural soil. If the transducer has thermal properties different from those of the soil, it will interfere with the natural heat transfer and an error in measurement will occur. An analysis of the error for a transducer placed in an infinite medium in steady-state conditions is made in terms of two non-dimensional parameters: (1) the ratio of transducer conductivity to soil conductivity and (2) the ratio of transducer thickness to transducer width. An exponential relationship is postulated on the basis of physical considerations and is verified by the results of an electrical analogy experiment for a square transducer having a thickness-width ratio of 0.125 for conductivity ratios from about 0.1 to 2.2. An error of -60 pct was found for a conductivity ratio of 0.1 and an error of $+5$ pct for a conductivity ratio of 2.2. The results are used to estimate error in measurements made during the Great Plains Turbulence Field Program.

Frank Press (Seismological Laboratory, California Institute of Technology, Pasadena, Calif.) *Velocity Distribution in the Crust*—Seismic determinations of crustal structure are sensitive to the vertical velocity distribution within the crust. This distribution is inherently difficult to observe. The available data are reviewed and new evidence is presented from the Corona blast of February 18, 1958. It is concluded that the upper part of the crust is characterized by compressional and shear velocities of 6 and 3.5–3.6 km/sec. Evidence is presented for a layer with compressional velocity of 7.2–7.4 km/sec occurring at a depth of about 20 km under California and Nevada. The implications of this layer on determination of crustal thickness by explosion seismology and surface wave phase velocity methods are discussed.

Donald R. Purdy (U.S. Naval Research Laboratory, Washington, D.C.) *Some Examples of the Variability of Winds at 300 mb*—Data from a limited number of transosonde flights have been processed to yield small-scale (two to five minutes) fluctuations in the winds. Spectrum analyses of these preliminary wind data are presented as well as the rates of turbulent dissipation of energy per unit mass ϵ. The latter were calculated using a formula developed by Batchelor relating ϵ to the mean-square acceleration of the winds.

R. O. Reid (Department of Oceanography and Meteorology, A and M College of Texas, College Station, Texas) *Effect of Coriolis Force on Edge Waves: I, Investigation of the Normal Modes*—Free edge waves on a sloping continental shelf in the presence of Coriolis force differ from purely gravitational edge waves in several important respects. In general, there exist two classes of waves for a given mode. The waves of the first class can move in either direction along shore; however, for a given longshore wave length, the speed for waves moving to the right (when facing the shore from the sea side) exceeds the speed of the waves which move to the left. The waves of the second class are essentially inertial boundary waves with very slow speed and, like Kelvin waves, move only to the left. Another important feature of edge waves on a rotating Earth is that the group velocity has a finite upper limit for waves of very great length. In the case of the fundamental mode of the first class (modified Stokes edge wave on a rotating Earth), the limiting group velocity is gs/f, where g is the acceleration due to gravity, s the shelf slope, and f the Coriolis parameter. For the fundamental mode, only the first-class waves can exist and the difference in magnitude of the phase velocities for propagation to the right or left is equal to f/k for any longshore wave number k.

Irvin C. Reigner (U.S. Forest Service, Northeastern Forest Experiment Station, Kingston, Pa.) *Prediction of Streamflow for Single-Watershed Calibration*—Six year's daily streamflow, precipitation, and temperature data were used to develop equations for the prediction of monthly and annual runoff, and peak flow from a 1500-acre scrub oak watershed in northeastern Pennsylvania. Standard errors of estimate were used to determine the length of streamflow records necessary to detect small differences in flow caused by converting the scrub oak cover to a high forest of mixed conifers and better hardwoods. Monthly streamflow was predicted using a weighted and exponential expression of monthly precipitation and an estimate of storage at the beginning of the month. The latter parameter was derived from an antecedent precipitation value and antecedent temperature. Annual streamflow prediction is based on the water balance equation: runoff = precipitation − water loss ± storage change. An equation has been derived using these independent variables: annual precipitation, mean annual temperature, and estimated storage change. The latter is the difference between beginning and ending storage, both derived as above. Peak flows were estimated from a multiple regression involving storm precipitation weighted on an hourly basis and a total storage factor derived as above.

Roger Revelle (Scripps Institution of Oceanography, University of California, La Jolla, Calif.) *The Downwind Expedition to the Southeast Pacific*—As part of the oceanographic program of the International Geophysical Year, the research vessels *Horizon* and *Spencer F. Baird* carried out, during the period October 21, 1957, to February 28, 1958, a voyage of exploration to the Southeast Pacific. The total distance logged by the two ships was about 40,000 miles. The program of investigation included measurements of atmospheric and oceanic carbon dioxide; studies of the chemical and physical properties of the water, including its carbon 14 content; bottom sounding, dredging, coring, and photography; and seismic refraction and reflection studies of crustal structure and thickness. Some 35 measurements of the heat flow through the sea floor indicate the existence of a definite pattern with high values near the East Pacific Rise and low values near the South American trenches and in some areas west of the Rise. The highest values were about 40 times the smallest. Seismic velocities greater than 7.5 km a second were not obtained in the region of highest heat flow. The echo sounding results indicate that the major features of the sea floor topography of the Southeast Pacific form a reticulate pattern of basins and ridges and are considerably more complicated than has previously been supposed. Guyots were found and dredged in several areas. The rate of sedimentation in much of the region seems to be very slow: in many places manganese nodules cover about a fourth of the bottom.

Oscar E. Richard (Headquarters, Air Weather Service, Directorate of Climatology, Andrews Air Force Base, Washington, D.C.) *Comparison of Methods of Computing Degree Days*—Recent work on the computing of degree days brought to light a distinct variance in the number of degree days computed for maritime stations using a method recently developed by R. G. McGrew, AWS, 2nd Weather Wing, Technical Support Branch, as against the method in more common use developed by H. C. S. Thom, U.S. Weather Bureau, about 1942. The two methods give comparable results for stations under a continental climatic influence. The results of a comparison of these methods against observed data will be presented here.

Adrian F. Richards (U.S. Navy Hydrographic Office, Washington 25, D.C.) and James M. Snodgrass (Scripps Institution of Oceanography, La Jolla, Calif.) *Volcano Acoustics*—Frequency analyses were made from magnetic tape recordings of airborne sounds originating from three volcanic eruptions. Both the September 1950 and January 1954 eruptions of Ō-sima Volcano, Japan (recorded by the NHK Broadcasting Bureau, Japan) were strong harmonic progressions with an apparent fundamental frequency of the first at 11 cycles and of the second at approximately 16–17 cycles. The lower limit of the analyses was ten cycles. Little indication of a resonant frequency appeared from the analysis of an eruption of Izalco Volcano, El Salvador (recorded by H. Young and L. Pugsley) in 1956; essentially broad-band acoustic energy was present from 20 cycles, the lower limit of analysis, to about 3000 cycles. All analyses made to date show energy maxima between about 100 and 200 cycles; however, the absence of maxima below this limit may result from instrumental attenuation of the low frequencies. Recent attempts to investigate underwater volcanic acoustics in the Pacific and Atlantic Oceans will be briefly discussed.

H. C. Riggs (U.S. Geological Survey, Washington 25, D.C.) *Regional Frequency of Low Flows of Streams*—The low-flow frequency relation based on observed minimum annual discharge at a gaging station is a function of stream-basin characteristics and of chance variation. Removal of the chance variation should adjust the relation so that it will better represent future events. This is done by using an equation which relates discharge at 20-year recurrence interval to (1) discharge at two-year recurrence interval, (2) drainage area, and (3) slope of the base-flow recession curve and in which the residual error of the correlation is largely due to chance variation. Such equations are presented for eastern United States. They may be used for stream sites having a minimum of discharge information as well as for gaged sites.

J. C. Rose, G. P. Woollard, and R. M. Iverson (Department of Geology, University of Wisconsin, Madison 6, Wisc.) *Gravity Standardization Measurements with the Gulf Pendulums in Australia and New Zealand*—The Gulf quartz pendulums have been used by the group at the University of Wisconsin for observations in the Pacific area and in the Antarctic. In 1956–1957 new Gulf stations were established at Christchurch, Wellington, Hastings, and Dunedin in New Zealand; Melbourne, Sydney, Brisbane, Townsville, Cairns, and Darwin in Australia; and Ross Island in the Antarctic. The sites at San Francisco and Honolulu were reoccupied. In 1958, observations were made at earlier Gulf sites at San Francisco, Honolulu, Manila, Tokyo, Darwin, Cairns, Townsville, Brisbane, Sydney, and Christchurch, and new Gulf stations were established at Okinawa, Hong Kong, and Singapore. The results appear to have an accuracy of ±0.5 mgal based on the standard error of the closure stations. The previous photographic recording methods have been changed to a completely electronic system using a photomultiplier and slit system with an electronic interval timer. This has resulted in great simplification in calculations of the results.

E. H. Roseboom, Jr., and G. Kullerud (Geophysical Laboratory, Carnegie Institution of Washington, Washington, D.C.) *The Solidus in the system Cu-Fe-S between 400 degrees and 800 degrees C*—The solid phases in equilibrium with a sulfur-rich melt and a vapor were determined by heating mixtures of the elements or of copper and iron sulfides plus sulfur in sealed and evacuated silica tubes with sulfur in sufficient excess to form a liquid as well as a vapor phase. Phases were identified by reflecting microscope and x-ray diffractometer. The phases encountered were pyrite, pyrrhotite, covellite, digenite, 'chalcopyrite-cubanite,' and the 'Cu_5FeS_6' phase described by Merwin and Lombard. The following pairs of phases are stable with a sulfur-rich melt and a vapor over the following temperature ranges: pyrite + covellite, $< 434 \pm 3°$; covellite + 'Cu_5FeS_6,' $434 \pm 3°$ to $485 \pm 2°$; 'Cu_5FeS_6' + pyrite, $434 \pm 3°$ to $498 \pm 4°$; covellite + Fe-bearing digenite, $485 \pm 2°$ to $507 \pm 2°$; Fe-bearing digenite + 'Cu_5FeS_6,' $485 \pm 2°$ to $498 \pm 4°$; Fe-bearing digenite + pyrite, $498 \pm 4°$ to $568 \pm 3°$; Fe-bearing digenite + 'chalcopyrite,' $568 \pm 3°$ to $>800°$; 'chalcopyrite-cubanite' + pyrite, $568 \pm 3°$ to $739 \pm 3°$; Cu-bearing pyrrhotite + pyrite, $739 \pm 3°$ to $743 \pm 3°$; 'chalcopyrite-cubanite' + pyrrhotite, $739 \pm 3°$ to >800.

Five phases are stable at each of the above temperatures, which represent invariant points. As the melt and vapor phases contain very little Cu and Fe, the pressure at these invariant points is probably slightly lower than that of pure saturated sulfur vapor. In the presence of a sulfur-rich liquid and a vapor at 739°C, the solubility of copper in pyrite is less than a half per cent by weight but exceeds three per cent in pyrrhotite. At 700°C, 'chalcopyrite-cubanite' forms a continuous phase from Cu_6Fe_4 to Cu_3Fe_7. Digenite forms a continuous phase to $Cu_{70}Fe_{30}$ at 700°C to $Cu_{82}Fe_{18}$ at 568°C, and to $Cu_{88}Fe_{12}$ at 500°C.

J. H. Rosenbaum (Shell Development Company, Houston, Texas) *A Note on the Propagation of a Sound Pulse in a Two-layer Liquid Medium*—The contribution from the branch line integral in Pekeris formulation of the propagation of explosive sound in a two layer liquid medium (Geol. Soc. Amer. Mem. 27, 1948) is investigated. It is shown that there is no net contribution to the solution, in terms of pressure amplitude measured in the upper layer, which decays less rapidly than r^{-2}, where r designates the horizontal range, which is large compared to the depth of the layer. This result is applicable to early arrival pressure signals and is in agreement with recently published model experiments by W. C. Knudsen in the Journal of the Acoustical Society of America.

R. D. Russell, R. M. Farquhar (University of Toronto, Toronto, Ont., Canada), and R. L. Stanton (The University, Armadale, New South Wales, Australia) *A Revised Interpretation of the Isotope Ratios of Common Lead*—It is well known that the model proposed by Alpher and Herman for the interpretation of common lead isotope abundances explains the essential features of these abundances. It is also known that small systematic deviations occur, which have been explained on various occasions by the extraction of lead systematically with time from rocks of different lead abundances, and by the systematic alteration of the proportions of these elements in a single source rock from which all leads may come. A basic difficulty in pursuing the nature of the deviations has been the uncertainties in identifying anomalous leads and excluding them from the analysis. In several papers published since 1955 by one of us (R. L. S.) a mechanism has been put forward for the genesis of a certain class of lead ores of the conformable type. It is an essential feature of this theory that the lead is derived directly from the Earth's mantle and formed into galenas; contact is made only with surface rocks of known types for a very limited period of time. Therefore, it follows that the probability of these leads having received anomalous additions of radiogenic lead from surface rocks is very small. We thus consider these leads to be primary and all vein leads to have travelled finite distances through surface rocks and therefore to be potentially anomalous.

Of the available lead isotope analyses we are able to find only a few that are of this conformable type. However, these leads all fit a single growth curve (that is, a single uranium-thorium-lead system) within a few tenths of one per cent. All the systematic deviations from a simple model referred to in the first paragraph vanish. One result of this hypothesis is that these galenas should be datable with excellent precision. There is a possibility that the class of leads we refer to here is the same as those described by Houtermans as 'B-type anomalous'.

O. A. Schaeffer and J. Zähringer (Chemistry Department, Brookhaven National Laboratory, Upton, L. I., N. Y.) *The Rare-Gas Contents of Iron Meteorites*—The rare gases in iron meteorites are present mainly as a result of nuclear reactions of cosmic-ray protons on the iron and nickel nuclei of the meteorites. At present, researches are being conducted to obtain information about the history and origin of meteorites by measuring the rare-gas contents of meteorites and measuring the production cross sections for the nuclear reactions of high-energy protons on iron which produce rare gases. The present level of mass spectrometric techniques is sufficient to study the reactions using high-energy protons from accelerators. We have been able to measure the cross sections of He^3 and He^4 production from iron for protons of 0.16, 0.43, and 3.0 Bev, as well as the cross sections for the argon and neon isotopes with 0.43 Bev protons. These results are used to interpret the rare-gas contents of several iron meteorites. Some results of this study are: (1) Present He^3-T ages should be lowered by a factor of 3, (2) a study of the A^{39} and Cl^{36} content of meteorites should yield information as to how long meteorites have been in space, and (3) from a study of He^3/He^4 ratios and especially Ne/He ratios it should be possible to obtain a depth-energy dependence of the rare-gas content and in this way possibly say something about the original size of meteorites when in space.

A. E. Scheidegger (Imperial Oil Limited, Calgary, Alberta, Canada) *Tectonophysical Significance of Fault-Plane Solutions of Earthquakes in the Northwest Pacific*—Fault-plane solutions of earthquakes are usually ambiguous to the extent that it is not known which of two orthogonal planes is the fault plane and which is the plane orthogonal to the motion vector (auxiliary plane). This makes it difficult to correlate fault plane solutions of earthquakes with tectonic features. To get around this difficulty, it has been proposed in the literature to investigate the B-axis, that is, the intersection of fault and auxiliary plane which is always uniquely defined. The writer has recently suggested in another paper, a physical significance for the B-axis by showing that the latter always lies in a plane normal to the axis of the tectonic displacement couple. This enables one to determine, from a series of fault-plane solutions of earthquakes in any one area, the tectonic displacement by a least-squares solution. This has been done for the areas marginal to the Northwest Pacific Ocean. In this fashion, the motion of the margin of the Northwest Pacific Ocean can be determined.

A. E. Scheidegger (Imperial Oil Ltd., 300 Ninth Avenue, West, Calgary, Alta., Canada) *The Random-Walk Model of Flow Through Porous Media*—Statistical methods have proven to be very successful in connection with the investigation of mixing effects that occur in ground-water flow. In pursuit of the idea of applying statistical mechanics to the theory of flow through porous media, the present paper investigates the implications of a random-walk model as opposed to random residence-time models. Although the random-walk model is physically not as satisfactory as other statistical models, it has the advantage of enabling one to investigate easily the effect of autocorrelation between subsequent time steps. It is shown that, if autocorrelation exists, the mixing process in porous media is governed by a telegraph equation rather than by a diffusivity equation. Expressions for the constants occurring in the telegraph equation are deduced in terms of other dynamical variables.

I. I. Schell (Tufts University, Medford, Mass.) *A Reconciliation of an Increased Circulation Characteristic of an Ice Age with a Decrease in Temperature and Solar Radiation*—It is shown that while an increase in the equator-to-pole temperature gradient and in the circulation could result from a simple increase in the temperature produced by an increase in the total solar radiation, a greatly increased equator-to-pole temperature gradient, circulation, evaporation, and precipitation characteristic of an Ice Age could occur only with a small decrease in temperature at the equator and large decrease at the poles produced by quite small but continuous decreases in the total solar radiation. It is estimated that the temperature during an Ice Age was −70°C at the North Pole and −100°C at the South Pole and that the temperature during an interglacial was 0°C and −30°C, respectively. This would permit ice in the Antarctic to exist during the entire period of the Pleistocene epoch as was previously indicated by Gould. It is also concluded from the uniform concentration of CO_2 over the globe, except for points near industrial sites, that changes in this gas could not account for the Ice Ages and for the recent amelioration in climates but may have slightly contributed to it.

G. F. Schilling and T. E. Sterne (Smithsonian Astrophysical Laboratory, Cambridge, Mass.) *Temperatures and Densities Inferred from Observations of USSR Satellites*—Surface observations of artificial earth satellites permit the application of relatively easy methods to calculate upper atmosphere densities from changes in the orbital elements due to drag effects. However, a substantial number of simplifying assumptions are implicitly involved in any such method developed to date, thus reducing the reliability of the results obtained from nonspherical satellites. Because of antenna effects, this includes all satellites which have been launched so far. Nevertheless, comparison of our numerical results based on observations of satellites 1957 $\alpha 1$, $\alpha 2$, and β, with those derived by other investigators, depicts a reasonable consistency which implies the need for a revision of existing model or standard atmospheres. It appears to us that the atmospheric density as well as the temperature above some 150 km altitude are appreciably higher than was usually thought before the availability of satellite data. In spite of the as yet low degree of accuracy of all numerical results, they necessarily influence not only the calculations of expected satellite life-times, but also the design characteristics for future satellites.

Allen H. Schooley (U.S. Naval Research Laboratory, Washington 25, D.C.) *Profiles of Wind-created Water-Waves in the Capillary-gravity Transition Region*—Crapper (1957) has theoretically predicted that pure capillary waves have profiles that peak downward, which is the reverse of the gravity wave case. This paper confirms Crapper's theory and shows enlarged profiles of capillary waves in a small water-wind tunnel that were photographed with a high-speed motion-picture camera. Under the conditions of the measurements, the maximum vertical distance between trough and crest for the capillary waves that were observed was about 0.5 wave length. This is roughly 70 pct of Crapper's theoretical figure of 0.73, and is about 3½ times the maximum of 0.14 for gravity waves. Wave profile pictures in the transition region from capillary to gravity waves are also shown. Examples are given where capillary waves having the same velocity as the gravity waves tend to ride just in front of the crests of the gravity waves.

Harry E. Schwarz (Corps of Engineers, U.S. Army, Washington 25, D.C.) *Simulation of a Reservoir System*—In developing river-regulation schemes, it is necessary to test the contemplated improvements and their operations against actual flow data to show the effects of the improvements. This usually is done by routing actual flows through the reservoir system. This gives an accurate picture of the operation of the system, but the method is time-consuming and not so well adaptable to the study of long time periods which are needed for conservation studies. Simplifying assumptions together with high-speed computation methods permit the simulation of a reservoir system in a form useful to the planning engineer. This paper describes a system of four reservoirs, one existing and three proposed, on the North Branch of the Potomac River, and develops a mathematical model of this reservoir system suitable for programming for an electronic computer of medium size.

A. L. Sharp (Agricultural Research Service, U.S. Department of Agriculture, Lincoln, Nebr.), A. E. Gibbs (U.S. Bureau of Reclamation, Lincoln, Nebr.), and W. J. Owen (U.S. Soil Conservation Service, Lincoln, Nebr.) *Problems Involved in Determining the Effects of Land Use and Treatment on Water Yields*—The disposition of precipitation and derivation of water yields as residuals are discussed. The parameters involved in these processes are enumerated and their effects explained. Problems involved in obtaining applicable data and computing results, with some possible methods of analysis, are considered. Use of plot and small-watershed data involves bridging the gap from small areas to large watersheds. The primary problem in determining effects of land use and treatment on water yields, from larger watersheds, stems from lack of directly applicable data. Large errors are probably involved in computation of watershed precipitation and determination of other factors. These errors increase inversely with the time period involved. It is possible to obtain at least periodic data on land use in watersheds, but obtaining quantitative data on the quality of vegetative cover is difficult. The number of variables involved in the generation of runoff is so great that use of electronic computers appears indicated in solutions of problems by multiple regression analysis.

Anatol J. Shneiderov (Polycultural Institution of America, 1241 New Hampshire Ave., Washington 6, D.C.) *On The Internal Temperature of the Earth*—A continuous influx of cosmic energy into the Earth has been determined as

$$E = k(2GM/rc^2)^2 \times (\beta Ms)^2 = 9 \times 10^{16}\ \text{ergs/sec} \qquad (1)$$

$k(2GM/rc^2)^2$ is gradient of pressure the flux produces in the Earth, G is gravitation constant, M is the mass, r is the radius, and δ is the mean density of the Earth, c is the velocity of light, β is the absorption constant of the flux (4×10^{-11} cm^2/gm), $s \oplus = 1 - (3/4)(r\delta\beta) + (2/5)(r\delta\beta)^2 - (1/6)(r\delta\beta)^3 + (2/35)(r\delta\beta)^4 - (1/60)(r\delta\beta)^5 \ldots$, and k being the unit of gradient in CGS system. Using the relationship $E' = \sigma T^{4\circ}K$, where $E' = E/4\pi r^2$, and σ is Stefan-Bolzman constant, T_{eff} of the Earth comes out 4.2°K, insolation and radioactive heat excluded, provided the entire influx of cosmic energy is radiated back into space. Heat flow from below the crust has been calculated to produce T_{eff}

of around 1°K. Therefore, about 3×10^{16} ergs are either stored in the interior of the Earth each second, or produce some geophysical work, or both. Checked for accuracy by calculating T_{eff} of over 80 various stars, and the planets, (1) produced values in satisfactory agreement with T_{eff} determined by other methods. Based on E' a formula for T as a function of δ' as density at a distance R from the center of the Earth has been developed

$$T = \{E'(b/\sigma)\,[0.5r^2(1 - R^2/r^2)]^{2/3}\}^{1/4} \quad \text{absolute degrees} \qquad (2)$$

b being a coefficient of proportionality. Expressed logarithmically for the Earth, (2) becomes

$$\log T\oplus = 0.424 + 0.5\log\delta' + 0.5\log s + (1/6)\log\{0.5r^2\,[1 - (R^2/r^2)]\}\,°\text{K} \qquad (3)$$

Assuming Bullen's distribution of density, (3) gives for T_{cent} 8900°K; surface of the core, 5770°K; and surface of the Earth 167°K if expenditure of energy for seismic and tectonic activities is not deducted. A curve of $T\oplus$ as a function of R and δ' has been drawn.

J. A. Simpson (Enrico Fermi Institute, University of Chicago, Chicago, Ill.) *Solar-Geophysical Aspects of Cosmic-Radiation Phenomena*—The intensity and energy spectrum of the cosmic radiation in the vicinity of the Earth changes dramatically within times ranging from the order of hours to the period of a solar cycle. The search for a theory of the solar origin for these cosmic ray changes with time is extending our knowledge of the solar influence upon electromagnetic conditions, both in interplanetary space and at the Earth.

John A. Simpson (Enrico Fermi Institute, University of Chicago, Chicago, Ill.) *What We Have Learned about Planetary Magnetic Fields and the Production of Cosmic Rays from the Flare of February 23, 1956*—This special flare event was unique for the magnitude of its cosmic-ray production and ionospheric effects at the Earth. From a detailed study of the solar flare, cosmic-ray propagation and storage in the solar system it is now clear that interplanetary magnetic fields exist. The available evidence favors an interplanetary field extending beyond the orbit of the earth. In addition, more intense fields exist in the vicinity of the sun which delay the escape of cosmic ray particles such that the delay depends upon particle energy.

R. H. Simpson (National Hurricane Research Project, U.S. Weather Bureau, West Palm Beach, Fla.) *Horizontal Eddies in the Hurricane Circulation*—Evidence of striated distributions of wind speed and of temperature in the hurricane circulation have been repeatedly found by research aircraft during the last several years. In 1957, simultaneous flights by two or more aircraft were made into hurricane Carrie on two occasions, once before and once after recurvature. Data collected on these occasions permit a more complete and quantitative examination of these striations and their role in hurricane circulations. The evidence is that this meso-scale feature is not a local result of convection in a rainband segment, but rather is a manifestation of a systematic eddy structure that permeates the circulation.

S. F. Singer (Physics Department, University of Maryland, College Park, Md.) *Role of Ringcurrent in Magnetic Storms*—E. N. Parker has thrown doubt on the existence of this ringcurrent. He concludes: (1) Even if it exists, the effects of the ringcurrent cannot be felt on Earth and therefore cannot give rise to magnetic storms because of the high conductivity of the Earth's outer atmosphere. (2) The main phase of magnetic storms can be explained in terms of an ionospheric current system. In our analysis of the problem of the origin of magnetic storms we reach conclusions which are directly opposite to those of Parker's. The main difference seems to be that we have considered the effect of a magnetic field on the anisotropic conductivity. In recent work, we investigated a physical mechanism (trapped protons drifting in the Earth's field) which produces an equatorial ringcurrent at a distance of five to ten Earth-radii.

H. F. Smith (Illinois State Water Survey, Urbana, Ill.) *The Effect of Urbanization on Runoff*—The hydrologic characteristics of two nearby watersheds, one urban, the other agricultural, have been compared. The two watersheds have similar relief and are comparable in area. The comparison shows that urbanization has considerable effect on peak flow, low flow, flow duration, and time of concentration.

J. B. Smith, Lela M. Jeffrey, and Donald W. Hood (Department of Oceanography and Meteorology, A. and M. College of Texas, College Station, Texas) *Evidence for the Presence of Carbamino Carboxylic Acids in Sea Water*—It has recently been observed in this laboratory that *Nitzchia closterium*, as well as other marine phytoplankton, utilize the carbamino complex of alanine in preference to inorganic carbon forms as a source of carbon for phytosynthesis. Since synthesis of significant amounts of carbon dioxide complex of alanine does not occur in water solutions except at pH values greater than 9.5, some doubt existed as to the significance of the observations to open sea conditions. Data have now been obtained which indicate that open sea water contains at least 5×10^{-8} moles of complex carbon dioxide per liter. The experimental procedure used to obtain these results were based on microbiological assay of organic concentrates isolated from sea water. The paper will include a discussion of the possible significance of these compounds to both the physical, chemical and biological systems in the sea.

Robert L. Smith, Irving Friedman, and William D. Long (U.S. Geological Survey, Washington 25, D.C.) *Welded Tuffs, Experimental I*—The authors investigated the welding and deformation rate of rhyolitic ash from the Bandelier formation of New Mexico as a function of temperature, water pressure, and load. The equipment allowed each of these variables to be varied independently. This paper will report on the results in the temperature range 535° to 735°C, H_2O pressure 50 to 300 lb/in², load of 100 to 528 lb/in², and times of from ten hours to five days. The maximum compaction of the starting material, 50 pct results in an obsidian-like black glass. Lesser amounts of compaction (shorter times) yields a glass ranging from a white loosely fritted mass, (~20 pct compaction) to a dark gray densely welded glass (>20 pct, <50 pct compaction). The rate of compaction (deformation) is strongly dependent on water pressure at water pressures from 0 to 50 pounds, and less strongly at higher water pressures. The rate dependence on water pressure increases at lower temperature.

W. Smith, I. Kaplan, and B. Herman (Office of Meteorological Research, U.S. Weather Bureau, Washington, D.C.) *The Life Cycle of the Meso-Systems Associated with the May 7–8, 1956 Severe Storms in Texas*—A detailed meso-analysis of a severe storm situation is presented with special attention given to the inception, the maximum intensity, and the dissipation of the meso-systems. Several features which may influence these phases of the life cycle are noted and possible implications presented.

Dewey R. Soltow and Richard D. Tarble (U.S. Weather Bureau, Washington 25, D.C.) *The Use of a Radar Beacon in Reporting Precipitation*—Increased use of radar has given hydrologists and meteorologists an excellent tool for improving the areal measurement of precipitation. It is often difficult to obtain rainfall reports from remote areas and during nighttime hours. As an aid in solving this problem, radar beacon techniques have been applied. As a result, a relatively inexpensive method of indicating accumulated precipitation on the PPI scope of the radar has been developed. Comparison of cost, maintenance, and reporting ability is made between the radar beacon and conventional radio-reporting raingages. Application of this type beacon to the reporting of river gage height and tide height is suggested.

William C. Spreen and Irving Solomon (Headquarters, Air Weather Service, Directorate of Climatology, Andrews Air Force Base, Washington, D.C.) *An Indirect Method for Estimating the Frequencies of Ceilings below Various Altitudes and within Various Altitude Ranges*—The solutions of many problems in applied climatology depend upon the further interpretation of available data through considerations of theory and a logical manipulation of the data. This paper describes an example of such a procedure whereby standard data summaries are arranged in a logical manner for a solution of the problem and, with further analysis based on background knowledge and theoretical concepts, reasonable estimates of values of unobserved parameters are attained.

Harris B. Stewart, Jr. (U.S. Coast and Geodetic Survey, Washington, D.C.) *Net Upstream Flow of Bottom Water in New York Harbor*—Approximately 100 hours of half-hourly measurements of current velocity and direction were obtained at the surface, mid-depth, and bottom at each of 17 stations arranged in four profiles across New York Harbor. Values for the velocity and duration of the flood and ebb currents allowed the calculation of the net non-tidal flow through the section represented by each meter. Net upstream movement near the bottom was found at each profile, with values ranging up to 19,000 ft^3/sec. At each profile the nontidal upstream flow subtracted from the nontidal downstream flow should represent the river flow at that time, and variations between profiles measured at different times should be attributable to changes in river flow. Comparison of the computed values with observed values from gaging stations metering river flow shows a lag between gaging and the arrival of a change of flow in the harbor. The rate of advance is about nine miles per day.

J. D. Stolarik, I. R. Shapiro, and J. P. Heppner (U.S. Naval Research Laboratory, Washington 25, D.C.) *The F-ΔD-ΔI Ground Station Magnetometers for Project Vanguard*—Analysis of satellite magnetic field measurements in terms of ionsopheric and extraterrestrial currents is dependent on accurate surface measurements taken reasonably close to the geographical locations where the satellite is interrogated. To obtain vector field measurements at the tracking-telemetering stations a magnetometer to measure absolute total field F, changes in declination ΔD, and changes in inclination ΔI was developed using a Varian proton precessional magnetometer as the sensing element. The reasons for undertaking this development were low cost, ease of installation and operation, and no calibration or temperature corrections. The magnetometers have been installed at Ft. Stewart, Georgia; San Diego, California; Havana, Cuba; Antigua Island; Quito, Ecuador; Lima, Peru; Antofagasta, Chile; Santiago, Chile; and Woomera, Australia. Errors in measurement are less than one gamma in total field, and less than 0.5 minute in declination and inclination. Operation of the magnetometers will be described.

G. W. Swenson, Jr. (University of Illinois, Urbana, Ill.) *Ionosphere Research Using Earth Satellites*—A review of the possibilities for the investigation of the morphology of the ionosphere by means of radio signals from man-made earth satellites. Several opportunities have already been presented, notably the launching of the USSR satellites transmitting on 20 and 40 mc/sec. Despite general lack of preparation at the time of launching and the lack of accurate orbital information throughout the radio life of these satellites, several interesting phenomena have been observed. Further opportunities are presented by the U.S. Satellites transmitting on 108 mc/sec, though the higher-frequency waves are much less affected by the ionosphere. Results obtained at the University of Illinois and elsewhere are discussed, and suggestions are made for future experiments. The possibility exists of determining the total electron content of the ionosphere, ionospheric inhomogeneities, and variation of ionospheric structure during normal and anomalous variations of solar radiation.

Howard E. Tatel[a], Merle A. Tuve, and Colleagues (Carnegie Institution of Washington, Washington 15, D.C.) *Carnegie Seismic Expedition to the Andes, 1957*—Because strong reflections were observed in 1954 and 1955 in the Rockies and Alaska from depths of 28 to 34 km, with high velocity rocks below this boundary (presumably the M-discontinuity), we undertook as our participation in the IGY a reconnaissance of the Andes Mountains and Plateau to seek evidence for the M-discontinuity under those high structures. Several open-pit copper mines at high elevations in Peru and Chile regularly use explosions of

---

[a] Deceased November 15, 1957.

30 to 70 tons, which served as wave sources. During August to November 1957, using seven mobile seismometer stations, approximately 210 recording sites in Peru, Bolivia, and Chile were occupied for 35 large shots at Toquepala, Peru, and eight large shots at Chuquicamata, Chile. Approximately 60 records were obtained with amplitudes above the ground unrest. The waves were very strongly attenuated in paths across (under) the high plateau, and no reflections or velocities at depth could be determined for these paths despite rather strenuous attempts. Explosions of 50 tons produced no vertical wave motion as large as ½ Angstrom unit at distances of 280 km across the plateau, for example. Parallel to the western edge of the plateau, however, and at moderate altitudes of 6000 to 10,000 ft, reflections and velocities were observed. In the general vicinity of Arequipa, Peru, the upper velocity was about 6.2 km/sec and reflections from what appears to be the M-discontinuity with mantle velocity under it, were observed from a depth of about 34 km under average elevations of roughly 10,000 ft. In Chile, under elevations of roughly 5000 ft toward Antofagasta and Taltal from Chuquicamata, the upper velocity is about 6.0 km/sec, there is a faint indication of a 6.8 km/sec structure below this, and strong reflections indicate an M-discontinuity at roughly 55 km depth, with the mantle directly below it. The structures under the Andes appear to be highly non-uniform.

MORRIS TEPPER (Office of Meteorological Research, U.S. Weather Bureau, Washington, D.C.) *The Formation of Atmospheric Gravity Waves on an Inversion Surface by the Transit of an Upper-Air Isotach Maximum*—The transit of a steady upper-air isotach maximum in a one-dimensional stratified atmosphere is shown to produce gravity waves on an underlying inversion surface. Other conditions being equal, waves of greater amplitude are favored by the more intense and slower moving isotach patterns. Synoptic implications are discussed.

SIDNEY TEWELES (Office of Meteorological Research, U.S. Weather Bureau, Washington, D.C.) *A Study of Anomalous Warming of the Stratosphere*—Cross-sections through stratospheric warm cells show relative positions of polar night jet stream, tropospheric jet stream, and the various stratospheric air masses. Apparent interrelationship between the various elements is shown by a model.

T. P. THAYER (U.S. Geological Survey, Washington 25, D.C.) *Some Problems Related to Dating Peridotites and Intrusive Serpentinites*—The development of serpentinite chilled borders on intrusive peridotites, as suggested by Bowen and Tuttle, and the mobility of serpentinous rocks under stress present many problems. Where contacts are sheared and contact metamorphism is obscure or absent, masses intruded magmatically and serpentinized in place may be indistinguishable from 'cold' serpentinite intrusions. Erosional debris in surrounding sediments, or relations of closely associated rocks such as gabbro, may be the only reliable means of dating emplacement of the original magma. Peridotites of one age may be indistinguishable from others, even in a small district. The term diapiric is suggested to distinguish serpentinous rocks probably intruded secondarily, or 'cold', from peridotite known to have been serpentinized in place. The problems are illustrated in eastern Oregon, where a peridotite-gabbro complex intrudes Upper Permian rocks, and serpentinite masses intrude Upper Triassic strata. The Upper Triassic strata lie across the complex in places, and contain gabbro and peridotite erosional debris. The complex, therefore, must have been intruded in Early or Middle Triassic time rather than Jurassic, as once supposed. The serpentinite masses in the Triassic strata are regarded as diapiric.

H. C. S. THOM (Office of Climatology, U.S. Weather Bureau, Washington, D.C.) *The Distribution of Annual Tropical Storm Frequency*—The frequency distribution of annual tropical storm and hurricane frequency is examined for the southern North Atlantic Ocean and for storms reaching the United States coast. On the basis of physical and statistical hypotheses, it is found that the negative binomial distribution provides very good estimates of probabilities. The time trend in tropical storm frequency is also examined and an explanation of its cause is proposed.

G. R. TILTON, G. L. DAVIS, AND G. W. WETHERILL (Carnegie Institution of Washington, Washington, D.C.) *The Age of the Baltimore Gneiss*—Zircon and microcline from the Baltimore gneiss near Baltimore give a Precambrian age while biotite from the same rock is dated as Paleozoic. Nearly concordant U-Pb ages for two samples of zircon and the Rb-Sr age of a microcline agree within the limits of error at about 1050 m y. Three samples of biotite have Rb-Sr ages of 305–320 m y, values which agree closely with a biotite K-A age determined by Wasserburg. To specify the history of the gneiss it is necessary to ascertain whether the zircon and microcline could have been detrital in origin. Such a possibility cannot be excluded for the zircon, but petrographic examination indicates that a detrital source for the microcline is improbable. It is believed that the rock crystallized 1050 m y ago and was subjected to metamorphism 305–320 m y ago. The biotite was formed or recrystallized at that time while the zircon and microcline preserved the record of the original age. These measurements extend the known occurrence of 1000 m y -old rocks in the Appalachian region as far south as Maryland. Indication of even further extent of these rocks is given by a biotite from Mary's Rock Tunnel, Shenandoah National Park, that has a Rb-Sr age of 900 m y.

KURT TOMAN (Geophysics Research Directorate, Air Force Cambridge Research Center, 415 Summer St., Boston, Mass.) *A Statistical Relationship between Sunspots and M-Regions*—A cross-correlation technique has been used between the final Zurich sunspot number Z and the planetary K-index ΣK_p. The period from 1940 to 1954 was investigated. One correlation interval contained 180 pairs of successive daily values, running means of 5, 10, 15, and 20. Employing the lag method, correlograms were found to be reasonably smooth, disclosing periodicities as related to the solar rotation and various displacements for optimum correlation. Under the assumption of a predominantly radial solar emission of particles and their constant mean travel time, these displacements were interpreted in terms of a relative longitudinal distribution of sunspots and M-regions.

Robert J. Uffen (Department of Geophysics, University of Western Ontario, London, Ont., Canada) *On the Origin of Rock Magma*—The remarkable correlation between the locations of ocean trenches, eugeosynclines, gravity anomalies, volcanic islands, and earthquake focii suggests a common origin. These phenomena are frequently interpreted as due to compressive failure of the outermost crust of the Earth. So Yoder's (1952) hypothesis has been extended to include remelting upon release of pressure during compressive, rather than tensile, failure. The mean pressure and corresponding melting ranges have been estimated for the materials of the crust, leading to the conclusion that the more basic magmas are generated at the greatest depths. The hypothesis is quantitatively feasible but the data, especially the actual temperature distribution, are inadequately known.

H. J. Van Hook (Department of Geophysics and Geochemistry, College of Mineral Industries, Pennsylvania State University, University Park, Pa.) *A Preliminary Report on the System Ag_2S-Bi_2S_3-PbS*—Liquidus, solidus, and subsolidus phase-equilibrium relations in the binary systems Ag_2S-Bi_2S_3, Ag_2S-PbS, Bi_2S_3-PbS, and $Ag_2S \cdot Bi_2S_3$-PbS are being investigated. The compounds Ag_2S (argentite), Bi_2S_3 (bismuthinite), and $Ag_2S \cdot Bi_2S_3$ (matildite) melt at 834 ± 5°C, and 801 ± 5°C, respectively, 'at the vapor pressure of the system'. A new compound, $Ag_2S \cdot 3Bi_2S_3$, has been synthesized below the solidus. Limits of solid solution between these phases have been determined as a function of temperature. Matildite undergoes a transformation at 180 ± 15°C, the high temperature form being isometric. Matildite and galena are completely miscible at the solidus and a miscibility gap is present at low temperatures. Presumably the low-temperature form of matildite is relatively insoluble in galena and this change of solubility with temperature is responsible for the common occurrence of matildite as an intergrowth with galena.

A. Walton and W. S. Broecker (Lamont Geological Observatory, Columbia University, Palisades, N.Y.) *Recent Results on the Ionium Method of Age Determination*—The Th^{230} (ionium) method has been used to estimate ages and sedimentation rates of deep-ocean sediments. Very few cores analyzed by the radium method have yielded ideal decay curves. The present investigations have been made to determine the reasons for the observed discrepancies. Core A-180-72, collected in the equatorial Atlantic Ocean (lat. 00°35.5′N, long. 21°47′W), has been investigated by total alpha, radon leakage, and radium measurements on various chemically and mechanically separated fractions. The non-carbonate fraction contains the majority of the radium and the results strongly suggest migration of radium. Both radon leakage and acid leaching experiments were used to distinguish between 'migrating' and 'fixed' radium.

The concentration of fixed radium in the non-carbonate fraction shows an approximate three-fold increase at a depth of about 20 cm. This depth marks the midpoint of the change from the relatively cold surface water temperatures of glacial times to the warm temperatures of recent times. C^{14} data indicate that this change occurred at about 11,000 years ago with a corresponding threefold decrease in the deposition rate of the non-carbonate fraction during recent times. The validity of these conclusions is currently being checked by direct Th^{230} measurements.

R. K. Wanless and G. B. Leech (Geological Survey of Canada, Ottawa, Canada) *Lead Isotope Studies of the Sullivan and Other Deposits in the East Kootenay District, Southeastern British Columbia*—The work reported here is part of a continuing program of the Canadian Geological Survey, planned to investigate isotopic variations and their relation to ore genesis and geological phenomena. The deposits studied occur in argillites and quartzites of Late Precambrian age and include the huge Sullivan ore body which is a replacement of certain beds within a single stratigraphic zone. The other deposits are small, and in further contrast, they are localized along fractures unrelated to stratigraphy. To date, 30 lead isotope determinations have been carried out. Of the samples, 21 are from the Sullivan deposit, representing widely separated parts of the ore body and varied mineralogical and structural environments within it. The average Pb^{206}/Pb^{204}, Pb^{207}/Pb^{204}, and Pb^{208}/Pb^{204} ratios determined are 16.66 ± .09, 15.59 ± .05, and 36.39 ± .12 respectively. The maximum variations are Pb^{206}/Pb^{204}, 2.9 pct; Pb^{207}/Pb^{204}, 2.7 pct, and Pb^{208}/Pb^{204}, 1.5 pct. On the other hand, galena specimens from most neighboring small deposits studied, which also occur in Precambrian formations, exhibit higher isotopic ratios than the Sullivan average and show substantial variation within the group. The striking constancy of the isotopic ratios indicates that the Sullivan lead was deposited from a single homogeneous source having a normal uranium-thorium content. The isotopic distribution in most of the smaller deposits, on the other hand, bears no relationship to that found in the Sullivan deposit.

H. W. Wells (Department of Terrestrial Magnetism, Carnegie Institution of Washington, Washington, D. C.) *Ionospheric Focusing at 40 Mc/s*—Signals from the first Soviet satellite (1957 Alpha) at 40.002 Mc/s were monitored at the Derwood (Maryland) Experimental Laboratory of the Carnegie Institution of Washington. The receiving instrument was a Ryle-type phase switching interferometer using folded dipole antennas separated about 12 wave lengths. A movement of any signal source through the antenna pattern produces the well-known interference structure with maxima and minima resulting from the addition or cancellation of the combined signals from the two antennas. The recorder was operated continuously for the collection of propagation data rather than orbital information. The results show the normal series of characteristic interference patterns separated by the 90 minute interval between successive transits. The report includes some conjecture on mechanisms for 'image' formation in the ionosphere and a discussion of other periods of 40 Mc/s interferometer signals when the satellite was well beyond the horizon.

M. Pat Wennekens (Marine Laboratory, University of Miami, Coral Gables, Fla.) *Hydrography of the*

Straits of Florida—The Straits of Florida can be subdivided into three hydrographic provinces: (1) Southern Straits where the hydrography and bathymetry are an integral part of the eastern Gulf of Mexico. Two water masses, Yucatan Water originating from the Carribbean and Continental Edge Water formed in the eastern Gulf merge to form the Florida Current. (2) Cay Sal Region, an area of hydrographic transition. The bathymetry between Cay Sal Bank and the Florida Keys disturbs the direction of flow between the shallow and deep water. Santaren and Nicholas channels are influenced by western Atlantic Water originating from the Old Bahama Channel. (3) Northern Straits where three water masses are observed: Yucatan, Continental Edge, and western Atlantic waters, the latter easily identified from its higher oxygen content. The sill depth of the Straits of Florida lies slightly lower than the average depth of the oxygen minimum being exactly within the average depth of the phosphate maximum.

C. A. Whitten (U. S. Coast and Geodetic Survey, Washington, 25, D.C.) *Distortion in Continental Triangulation*—The present network of triangulation in the United States is the result of adding individual surveys season by season to the existing framework. The last major readjustment of the national net was in 1927. The skeleton framework of that date is now covered by crisscrossing arcs and area nets of first- and modified second-order triangulation. When each survey is mathematically adjusted to be consistent with the previously adjusted surveys, small twists and strains are introduced. These tend to accumulate through successive adjustments to a point where observations are distorted far beyond normal expected errors. Efforts are made to keep this distortion to a minimum by increasing standards of accuracy for the basic framework and by planning surveys to give strength to the net as well as furnishing desired information for engineering and scientific projects. Methods of computation which will give complete information on internal accuracy and checks must be used. Also, through the application of modern electronic computing equipment, it is possible to adjust the maximum size net, thereby reducing probability of extreme distortion.

David E. Willis, Robert C. Fitzpatrick, and J. T. Wilson (University of Michigan Engineering Research Institute, Ann Arbor, Mich.) *Some Observations on the Rainier Underground Nuclear Detonation*—Observations were made using standard low-frequency refraction geophones. The outputs of several configurations of geophones were recorded on magnetic tape. A 5-cps low-pass filter was used to improve signal to noise ratio. The unfiltered output of a single geophone sitting on a concrete pad was fed into a unique seismic level recorder. The output of this was recorded on an Esterline-Angus pen recorder. Level recorder data indicate prominent P, S, L_g, and L_r waves. Analysis of the magnetic tape recorded data indicates frequencies higher than those normally expected to be propagated over long distances.

John W. Winchester (Massachusetts Institute of Technology, Cambridge, Mass.) *Sodium and Potassium Determination by Neutron Activation*—For a wide variety of common rocks and minerals, virtually all of the radioactivity induced by a short thermal neutron irradiation and remaining 48 hours after irradiation is due to sodium and potassium. The active species are 15-hour Na-24 ($E_\beta = 1.4$ Mev, $E_\gamma = 2.75, 1.37$ Mev), and 12.5-hour K-42$_\gamma$ ($E_\beta = 3.5$ Mev, $E_\gamma = 1.5$ Mev present in ten per cent of the decays). By selective β and γ counting the amounts of each active species can be measured separately. It is then possible to determine sodium and potassium in many rocks by pile neutron irradiation of samples and standards followed by counting of the induced radioactivity without prior chemical processing. A test experiment for the determination of potassium in granite, gabbro, shale, clay, feldspar, biotite, muscovite, and lepidolite using a K_2CO_3 reference standard gave potassium contents with a few per cent accuracy by selective β-counting with an end-window proportional counter and aluminum absorbers. The principal source of error was in counting, especially in determining the γ-ray contribution from Na-24 to the total counting rate. Improved counting techniques should lead to much more accurate potassium determinations and the method should be rapid and free from chemical contamination.

J. Lamar Worzel (Lamont Geological Observatory, Columbia University, Palisades, N.Y.) *Gravity Measurements on a Surface Ship with the Graf Sea Gravimeter*—Gravity measurements have been made aboard the surface ship *U.S.S. Compass Island* (EAG 153) with the Graf sea gravimeter mounted on a stabilized platform. On the first cruise a line of submarine gravity measurements was repeated and discrepancies of the order of the navigational errors occurred. Many additional measurements made on subsequent cruises agree satisfactorily where they cross lines of previous submarine measurements. Crossings of our own track give better agreement than crossings of the submarine tracks, due to superior navigation.

It is not yet possible to state in what sea states such gravity measurements can be made since difficulties with the operation of the stable platform have made it indeterminate whether the inadequate operation is due to the stable platform or the gravimeter for the rougher seas. The problem of measuring the Eötvös correction is more severe for a surface ship with larger windage and subject to the larger currents which exist at the sea surface than with a submarine. The location of the observation points remains as one of the most serious difficulties of gravity measurements at sea. Nevertheless, the Graf sea gravimeter shows great promise as an instrument to measure gravity at sea from a surface ship. Whether similar results can be obtained from smaller ships remains to be seen. Tests of this question will be made in the near future.

P. J. Wyllie (Department of Geophysics and Geochemistry, College of Mineral Industries, Pennsylvania State University, University Park, Pa.) *The Fusion of Torridonian Sediments by a Picrite Sill in Soay* (*The Hebrides*)—Progressive thermal metamorphism of Torridonian arkose by a small picrite sill has culminated in extensive fusion. From chemical and modal analyses of a fused xenolith the composition of the liquid developed at the stage of maximum fusion was calculated. For this composition a liquidus *PT* curve was obtained by estimating isobaric liquidus temperatures from data in the system orthoclase-albite-silica-water. Since tridymite crystallized from the liquid the maximum pressure is given by the intersection of the estimated *PT* curve with the experimentally determined *PT* curve for the inversion quartz $\rightleftharpoons$ tridymite (in the presence of water vapor). This provides a minimum estimate of 1025°C for the temperature attained by the liquid. The stage of maximum fusion occurred when crystallization of the picrite was almost completed. By analogy with the Karroo dolerites the picrite intrusion temperature may have been 150°C higher than the maximum temperature of the liquid. A *PT* curve for the picrite intrusion temperature, 150°C higher than the estimated *PT* curve for the liquid, gives a minimum temperature of 1175°C and a maximum of 1460°C (at atmospheric pressure). No independent estimate of pressure is available. The picrite is an ultrabasic rock containing 50 to 60 pct of olivine. Its estimated intrusion temperature is higher than that of many other ultrabasic minor intrusions, and higher than would be expected if the sill were emplaced as a largely crystalline magma.

P. J. Wyllie and O. F. Tuttle (Department of Geophysics and Geochemistry, College of Mineral Industries, Pennsylvania State University, University Park, Pa.) *Hydrothermal Experiments on the Melting Temperatures of Shales*—The partial fusion of many sediments will produce some granitic liquid and it is often assumed that shales are the lowest melting rocks in geosynclinal sections. It has been suggested that all magmatic rocks could be generated by the fusion of different sediments, and Oftedahl (1957) suggested specifically that the fusion of shales at granite contacts could produce basaltic liquids. For these reasons the hydrothermal melting relations of five analyzed shales were investigated. The *PT* curve for the beginning of melting of the shales is only 20°C to 40°C higher than the corresponding curve for granites. At temperatures 150°C higher the shales consist of about 50 pct of liquid. At these temperatures many natural granites would be completely liquid. The granitic composition of the quenched liquid is shown by its refractive index (about 1.504). The *PT* curve for the beginning of melting of basalts in the presence of water vapor lies 150–200°C above the similar *PT* curve for granites and it is unlikely that granite liquids would be superheated to the extent necessary to produce basalt liquid by fusion of shale as suggested by Oftedahl. The temperature and heat source in itself is a formidable problem and, when coupled with the chemical differences between basalts and shales, there is little likelihood that basaltic liquids could be produced at granite contacts by fusion of shale. The fusion of shales over a wide *PT* range will produce liquids of granitic composition but complete or partial fusion will not produce basaltic magmas. The nature of the phase or phases (that is, plagioclase, cordierite, pyroxene, etc.) developed during the melting indicates gross chemical characteristics of shales.

Bernard Zellner and Carl D. Eklund (Tennessee Valley Authority, Knoxville, Tenn.) *Hydrologic Effects of Land Use and Vegetation in the Chestuee and Beech River Watersheds in Tennessee*—In the Chestuee Creek and Beech River watersheds in Tennessee, TVA and other interested Federal, state and local agencies are working with the local people in a program to promote improved land use and management. Assistance to the people seeks increased crop and forest production and efficient utilization of water. The effects of cover and management on water relationship are being measured. Hydrologic records have been kept in the Chestuee Creek watershed since January 1944. Land-use surveys in April 1944 and April 1954 form a basis for comparing vegetative changes with changes in the watershed hydrology, particularly the reduction of sediment loads. Hydrologic measurements in the Beech River watershed began in January 1953. Representative farms were surveyed for land use in 1950, and a comprehensive land-use study was made on one subwatershed in 1954. The information thus obtained will be used as an index to improvements in land management. Experimental research and demonstration on a small watershed in the area have gone on for over 15 years and demonstrate the efficiency of reforestation.

B. D. Zetler, H. B. Stewart, Jr., and C. B. Taylor (U. S. Coast and Geodetic Survey, Washington, D.C.) *Recent Ocean Temperature and Sea-Level Anomalies on the West Coast*—The rise in water temperatures and sea level along the west coast during the past six months is linked to a change in the surface geostrophic winds. The water temperature change results both from reduced upwelling and the resulting reduction in geostrophic current. Lower sea level along the coast is described as maintained at an equilibrium during strong upwelling. Sea level then rises as this equilibrium is upset by the reduction in the northerly component of the winds. Presumably stronger west winds contribute to even higher peaks during early 1958.

Alfred J. Zmuda (Applied Physics Laboratory, Johns Hopkins University, Silver Spring, Md.) *A Method of Analyzing Values of the Scalar Magnetic Intensity*—Various studies on the interaction between charged particles and the geomagnetic field indicate the existence of a source of magnetism located above the Earth's surface. It is likely that for the near future, magnetic studies connected with the external source and with upper-air magnetic properties in general will be conducted primarily with magnetometers measuring only the magnitude of the intensity, not its direction. With this type of data the customary methods of analysis are not applicable. An appropriate analytic method is treated which utilizes a series for the square of the scalar magnetic intensity. The terms of this series are obtained through the use of the series of spherical harmonics generally applied to each component of the intensity. Through an analysis of scalar intensity alone, the method yields the magnetic characteristics that are normally obtainable through a spherical harmonic analysis of the vector magnetic intensity. Also, the variation with altitude of the magnetic equator is treated in conjunction with the location of the equator for cosmic rays.

Abstracts of the papers presented at the Pacific Southwest Regional Meeting, Pasadena, California, February 6–7, 1958, listed in the order of the last name of the first author

CARL S. BENSON (Division of Geological Sciences, California Institute of Technology, Pasadena, Calif.) *Physical Investigations on the Snow and Firn of Northwest Greenland during 1952, 1953, and 1954*—The Greenland Ice Sheet is a single monomineralic rock formation. The bulk of the formation is metamorphic but it is covered by a thin (maximum thickness approximately 85 m or 270 ft) sedimentary veneer of snow and firn. This sedimentary member is perennial above the firn line; and its history may be deciphered by the methods of classical stratigraphy and sedimentation. During a period of three years 118 test sites (82 pits and 85 supplementary ramsonde profiles) were studied along a 300-mi traverse, extending from 2000 to 8000 ft above sea level in northwestern Greenland. Measurements of temperature, density, ramsonde hardness, and grain size were made on the various firn strata at each pit. This work is part of the arctic research program of the Snow, Ice and Permafrost Research Establishment (SIPRE), Corps of Engineers, Wilmette, Illinois.

The following three facies are recognized within the perennial sedimentary firn: (1) The soaked facies which has been completely soaked with water during the melting season. It extends from the firn line to the uppermost limit of complete saturation, the saturation line. (2) The percolation facies which is subjected to localized percolation of melt water from the surface without becoming saturated. It extends from the saturation line upward to the limit of surface melting, or the dry-snow line. (3) The dry snow (firn) facies upon which no melting occurs. It extends from the dry-snow line to the crest of the Greenland Ice Sheet. The saturation line gives rise to discontinuities in temperature, density, and ramsonde data, and may also be located by examination of the strata in pits. It is as sharply defined as the firn line, but the dry-snow line, although determined by the same methods, is more a zone of transition. This percolation can occur in snow or firn of subfreezing temperature. Stratification of firn results from variations in the conditions of deposition and subsequent diagenesis. Summer firn layers have lower density and hardness values and coarser grain size than winter layers; they may also show evidence of surface melt. The onset of fall and early winter is often identified by an abrupt increase in density and hardness together with a decrease in grain size. The identification of seasonal layers gives a measure of annual accumulation. The data indicate that the nourishment of the ice sheet is entirely by cyclonic storms and that precipitation in this region is about five times greater than that recorded at Thule. This difference is only partly a result of local topography. The Thule records are believed to be in error because the standard precipitation gage is not adequate for measuring snow storm precipitation.

FREDERIC A. BERRY (Aerometric Research, Inc., Santa Barbara, Calif.; formerly Advisory Committee on Weather Control, Washington, D.C.) *Results of the Evaluation Program of the Advisory Committee on Weather Control*—The Advisory Committee on Weather Control was established by act of Congress in 1953, and directed to make "a complete study and evaluation of public and private experiments in weather control for the purpose of determining the extent to which the United States should experiment with, engage in, or regulate activities designed to control weather." The Committee, operating with a modest budget and for only a brief period of time, concentrated its efforts on an attempt to evaluate the results of cloudseeding operations using silver iodide smoke generators, both by statistical methods and a program of small-scale field experiments. In its final report, submitted to the President on December 31, 1957, the Committee reported, among other things, that in its opinion the seeding of winter-type storm clouds in mountainous areas of the western United States had produced an average increase in precipitation of 10 to 15 pct from the seeded storms. The Committee recommends the establishment of a long-term research program designed to provide the foundation of fundamental knowledge of the physical and chemical processes in the atmosphere necessary for a more effective practice of weather modification.

MAX BOOKMAN AND LUCIAN J. MEYERS (California Department of Water Resources, Los Angeles, Calif.) *San Diego's Future Water Requirements*—San Diego County is one of the fastest growing areas in the nation. During the decade 1940 to 1950, the population doubled and has now tripled since 1940. It is estimated that the number of people will continue to increase so that in 50 years there may be 2½ million people in San Diego County or three times the present population. Today this area is largely dependent on limited imported water supplies and in view of the potential growth, keeping pace with the accelerated demands for more water is an important major consideration. This presentation depicts the results of a recently completed detailed study made by the California Department of Water Resources of the market demands for water in San Diego County. These studies included projections of probable future population growth; economic studies of the future of irrigated agriculture, industry, and commerce; field studies of land use potentials with reference to adaptability of the land to crops and to urban and suburban developments; studies of the ability to pay for water by crops climatically adapted to the area; and a determination of unit uses of water by urban, suburban, and agricultural entities. The future water requirements for San Diego County were thus determined and the interesting results give an indication of what southern California and the State of California as a whole may expect to face in the immediate future in respect to their requirements for supplemental water supplies.

ROBERT H. BORN (California Department of Water Resources, Los Angeles, Calif.) *Effect of Recent Urbanization on Orange County Water Requirements*—This discussion will present results of recently completed studies by the California Department of Water Resources on the water requirements of Orange County as affected by rapid land use changes and other growth dynamics. Of significant interest are the extensive changes from agricultural development to urban and suburban development which has resulted in greater utilization of both local and imported water supplies. In areas such as Orange County, where expansion and change in the cultural development is accelerated, the periodic evaluation of water utilization is essential for planning future developments required to maintain adequate water supplies and the timing of their construction.

Frederick A. Brooks (University of California, Davis, Calif.) *Remarks on Heat Flow in Sandy Soils*—In spite of difficulties with soil moisture the use of Fourier analysis leads to significant determinations of heat penetration and loss rates in the ground and invites the calculation of the important half-cycle heat storage which depends on an unfamiliar thermal property of the soil, $\sqrt{kC}$, namely the square root of the product of thermal conductivity and volumetric heat capacity. The deep-soil temperature records of Alfred Smith carried out in Davis, California, 1932–1935 have been reinterpreted. These include four years of continuous weekly recordings from 4- to 12-ft depth and the year's record of day and night temperatures from the surface to 36-inch depth. The curves presented have considerable significance for regions of dry summer climate in that, in contrast to the published deep-soil temperatures in Europe, these show very sharp rise in soil temperatures in May following the fully developed winter minimums with no more than occasional, superficial freezing.

Recent work in Holland and Australia on moisture transport in soils now provides theoretical background for laboratory measurements of thermal conductivity of soils such as reported by Kersten, and also for measurements by S. Richards at Riverside of nocturnal moisture loss from the soil which we previously reported as amounting in heat to about ten per cent of the net nocturnal radiation rate. De Vries treats the transport of heat by evaporation and recondensation along a temperature gradient as a pseudo heat conduction which above 60°C exceeds heat conduction by liquid water. The thermal conductivity curves calculated by De Vries for a few of the Kersten samples are presented and also the curve for Yolo light clay soil (from Davis, California) reported by Philip. It is to be noted that by using their coordinate of volume-fraction-of-water it is possible to include on a single graph the thermal conductivity of peat soil in meaningful relation with the conductivities of sandy soils.

Norman H. Brooks (California Institute of Technology, Pasadena, Calif.) *Laboratory Studies of Dunes in Streams*—The hydraulic roughness of alluvial streams depends largely on the configuration of the bed, which may range from being flat to being covered with large dunes. During variable flow conditions the bed pattern and roughness of a given stream may change considerably, and should not be considered constant. Laboratory flume experiments were made to study the behavior of dunes in a bed of fine sand. Dune heights and wave lengths were measured, but it was found that they were not simply related to the observed friction factors. At high velocities the dunes become unstable and the bed is rapidly leveled out. The actual mechanisms of dune growth and movement were studied by means of high-speed and time-lapse motion pictures. A seven-minute film illustrating various features has been prepared for showing at the meeting.

R. H. Burgy and C. R. Pomeroy (Department of Irrigation. University of California, Davis, Calif.) *Interception Losses in Grassy Vegetation*—Interception of precipitation by various vegetative types is an important factor in the disposal of precipitation. Watershed management research to evaluate the effects of modifications of vegetation on the runoff must include more specific information on this important factor than is now available. In view of the paucity of information on this subject a laboratory technique utilizing plants grown in nutrient solution has been developed to accurately evaluate interception losses and related phenomena in grass plots.

Although the intercepted moisture that remains on the vegetative canopy during and at the end of a period of precipitation is subject to evaporation into the atmosphere, it does not necessarily follow that this is a complete loss to the plant, soil, water complex. It was found that in the case of a vigorously growing and transpiring crop the evaporation of a given amount of intercepted precipitation from the leaf surfaces involved was accompanied by a reduction of evapotranspiration in a like amount. The total loss of moisture, when considering the full system of plant, soil and water, was approximately the same in grass plots with both wet and dry leaf surfaces. The interception storage component and precipitation passing through the vegetative canopy as stem flow (S), through fall (T), or drip (D) were measured to determine the relationships and magnitudes. Storage capacities were observed to agree essentially with those reported by other investigators although some variations can occur with different storm types and intensities. S-T-D values were found to be quite significant even at the beginning of small storms.

Stanley N. Davis (Stanford University, Palo Alto, Calif.) *Changes in Salinity in Ground-Water Basins*—Ground water is subject to slow changes of chemical quality particularly within hydrologic basins which have been placed under irrigation. The changes can be expressed by differential equations in which the rate of change of a particular ion concentration is equal to the rate of ion inflow into the basin minus the rate of ion outflow plus or minus the rate of ion precipitation, solution, or exchange. If perfect mixing were to take place, accumulation of most ions would not be harmful in ground-water basins which have significant exterior drainage. Unfortunately perfect mixing is not achieved, and areas of excess salinity are formed in various parts of large basins. Methods of estimating local changes of salinity are presented; however field application awaits the collection of hydrologic and geochemical data of more detail than is presently available.

Hans A. Einstein (University of California, Berkeley, Calif.) and **Huon Li** (University of Pennsylvania, Philadelphia, Pa.) *Why do Secondary Currents Occur in Straight Channels?*—The existence of straight uniform flows without secondary current is studied. It is shown that laminar flows of this kind can remain without secondary currents independent of cross section and velocity distribution. For turbulent flows it is shown that secondary flows will develop spontaneously if in any part of the section the expression for $\frac{\partial \xi}{\partial t}$ as given in Eq. (19) is not vanishing.

GIFFORD C. EWING AND FRED B. PHLEGER (Scripps Institution of Oceanography, La Jolla, Calif.) *Tidal Influence on the Spacing of Inlets into Coastal Lagoons*—A common type of coastal configuration is one in which a long, narrow tidal lagoon of fairly uniform cross section lies parallel to the coast separated from the ocean by a low, sandy barrier island. It is frequently found that the barrier island of this type of lagoon is interrupted by inlets at more or less regular intervals of the order of 15 mi. The hypothesis is developed that this characteristic interval is determined by the variation in the hydraulic head which is developed across the barrier by the phase relation between the tide inside the lagoon and on the outer beach. Supporting evidence is presented based on tidal studies of Santo Domingo Lagoon in the arid region of Baja California.

LLOYD C. FOWLER (California Department of Water Resources, Los Angeles, Calif.; formerly Missouri River Division, Corps of Engineers, Omaha, Nebr.) *A note on the Intriguing Variation in the von Karman Universal Constant in Rivers*—The von Karman universal constant, kappa, in the logarithmic velocity distribution equation has been determined from laboratory experiment with clear water to be close to 0.4. Measurements in both the field and the laboratory of the velocity distributions in sediment laden waters flowing over a movable bed have shown that the value of kappa is less than 0.4. Further, these same measurements indicate that it is not a constant. However, field measurements by the U.S. Army Corps of Engineers of velocity distributions indicate that for large clear water rivers with nonmovable beds, the kappa value is about 0.4.

EDWARD D. GOLDBERG AND ROBERT W. REX (Scripps Institution of Oceanography, La Jolla, Calif.) *Contribution of Airborne Particles to Pelagic Sediments*—The quartz contents of pelagic clays from the eastern Pacific Ocean show a marked latitudinal dependence with a maximum around 30°N. Present evidences indicate that the quartz is mainly transported to the deposits through the atmosphere and that the observed distribution is probably related to the latitudinal values of the atmospheric wind fluxes and exposed arid land areas. A number of sediments display a distinct change in quartz content with depth. In all cases, there is a marked decrease going from the recent to the older strata. It is suggested that the changes indicate a major climatic change that occurred sometime during the Late Tertiary.

G. EARL HARBECK, JR. (U. S. Geological Survey, Denver, Colo.) *Evaporation Suppression—A Progress Report*—Studies of methods of suppressing reservoir evaporation by the use of a monomolecular film were begun in 1956 by the U. S. Geological Survey in cooperation with the Southwest Water Evaporation Research Council of Texas. Approximately 150 chemical compounds were screened in the laboratory by Southwest Research Institute. The most promising of these were tested on a small ranch pond near San Antonio and on a natural lake near Liberty, Texas. Provisional results indicate that evaporation from the ranch pond was reduced 18 pct during a three-week period in October. Further studies are underway at two other reservoirs in Texas. Techniques have been developed for the evaluation of the savings in evaporation by the use of a combination of the energy budget and mass transfer methods for measuring evaporation. The required calibration periods have been completed at these two reservoirs and a film has been applied to one of them.

EVERETT D. HOWE (Division of Mechanical Engineering, University of California, Berkeley, Calif.) *Status of Sea-Water Conversion Research*—The production of fresh water from sea water or other saline sources has been under intensive study in the United States since 1951, when the California Legislature appropriated funds for the University of California to undertake work in this field. The following year a Federal program was set up by Congress and has been administered by the Office of Saline Water in the U. S. Department of the Interior. This office appropriates money for experimentation by colleges, research organizations, industrial firms, and individuals on a contract basis and publishes the results. The office also provides coordination with other countries, as exemplified by the International Symposium held in Washington last November. The paper attempts to summarize not only the progress made in the University of California program but also status of research being done elsewhere.

Research programs have been directed at many different separatory processes since there are several physico-chemical phenomena which may be utilized. The schemes which have received attention include the well-known multi-effect and vapor compression distillation methods, freezing, use of solar heat, osmotic membrane applications, electrolysis, ion exchange, and solvent extraction. The objective of all of the programs is to develop a scheme which will produce fresh water at a price of $100 per acre foot or less, which would be competitive with some municipal sources. Multi-effect distillation and vapor compression distillation are the only two methods which have reached a truly commercial phase at this time, and are both too expensive in their present forms. Radical changes in design and operation of these plants have been proposed which could result in costs sufficiently low to be interesting. Certain pilot plant tests are now under way on these proposals.

Electro-dialysis is presently on a semi-commercial basis in that a number of installations are now operating the largest one being now constructed in South Africa having a capacity of some 3,000,000 gpd. This method seems very promising for demineralizing waters containing about ten per cent of the mineral concentration found in sea water. Freezing methods using the freeze-evaporation principle at low pressures seem to have considerable merit and are being studied by several investigators. The most economical method for separating the ice from the brine is that of counter-current washing. This scheme is still in the glassware laboratory phase. Solvent extraction, osmotic devices, and others to be discussed are still in early stages of development and cannot be accurately evaluated as yet. Developments of the past six years have resulted in a reduction of estimated minimum costs from over $400 per acre foot to slightly more than $100 per acre foot. The next two years should see the firming up of costs for at least five potentially low-cost schemes.

C. E. JACOB (P. O. Box 347, Northridge, Calif.) *Salt-Water Encroachment in Horizontal Confined Aquifers of Uniform Thickness*—The theory of steady states of opposed and parallel flows is outlined. Two simultaneous partial differential equations are obtained by using the method of Dupuit in both salt and fresh-water flows. Nonsteady states of flow are treated by numerical and graphical integration between neighboring steady-state solutions, assuming that a nonsteady flow may be approximated by a continuous succession of steady states. The validity of this approximation is tested. Simultaneous finite difference equations are set up for treatment by electronic analog. The theory is applied to typical coastal ground-water reservoirs. The sketchily known histories of encroachment are recapitulated as closely as possible.

JOHN KNAUSS (Scripps Institution of Oceanography, La Jolla, Calif.) *Variations in the Trade Winds and Changes in the Pacific Equatorial Countercurrent*—Because of the large amount of new observational data on the Pacific Equatorial Countercurrent it is now possible to describe the seasonal and spatial changes in this current with some certainty. The picture of the current that results from this analysis is compared with the structure of the Countercurrent as predicted from different theoretical models which have been proposed. It is shown that the Sverdrup model (1947) provides the best agreement.

BEN E. LOFGREN (Ground Water Branch, U. S. Geological Survey, Sacramento, Calif.) *Near-Surface Land Subsidence in Western San Joaquin Valley, California*—Numerous evidences of land subsidence have been observed on certain lands in the San Joaquin Valley immediately after the application of water. Extensive settlement and soil cracking occur along ditches or where water accumulates in ponds; and irregular, undulating surfaces develop when irrigation is attempted. Detailed experiments are being made on quarter-acre test plots in western Fresno County by the Inter-Agency Committee on Land Subsidence in the San Joaquin Valley. The rate of water infiltration is being measured, as is the rate of subsidence of bench marks located on the surface and at various depths down to 300 ft. As of October 24, 1957, after 385 days of operation of Test Plot B, surface bench marks had settled an average of 8.77 ft; the bench mark at a 25-ft depth had settled 7.95 ft; the 50-ft bench mark, 6.63 ft; the 75-ft bench mark, 4.87 ft; and the 100-ft bench mark, 2.82 ft. The 150-ft bench mark had not yet registered a movement; however, settlement at this depth is anticipated soon. Infiltration at a continuing rate of 0.25 ft of water per day has been more than sufficient to fill the pore space beneath the test plot to the wetted depth, indicating that considerable lateral spreading of the water has occurred. Cored samples collected before and during the spreading operation show the increase in density and moisture content to a depth of 120 ft. The low density of the alluvial sediments and their extreme dryness apparently are two important factors in the land subsidence resulting from application of water in the area.

ROBERT A. MERRIAM AND EVERETT L. HAMILTON (California Forest and Range Experiment Station, U. S. Forest Service—California Division of Forestry, Glendora, Calif.) *Effects of Fire on Streamflow in Grass Woodland Watersheds in the Central Sierra*—Several gaged small watersheds of about 25 ac in the woodland-grass range land of the Sierra Nevada foothills were burned in a summer wildfire in 1951. Streamflow characteristics during two years following the fire are compared with those during a pre-fire calibration period. Storm peak discharges were related statistically to rainfall quantity and rate variables by multiple correlation analyses. No effect of the fire on storm peak discharge was detected. Total streamflow yield during the first post-fire year, as well as summer spring flow from one watershed, were similar to two pre-fire years with comparable rainfall. No measurable sediment was deposited in the debris basins following the fire. The reasons for the lack of effect of this fire on streamflow are the failure of the fire to consume the woody vegetation, the herbaceous ground cover or the mulch on the soil surface, and the rapid regrowth of annual herbaceous plants.

SETH B. NICHOLSON (Mount Wilson Observatory, CIW, and Palomar Observatory, CIT, Pasadena, Calif.) and OLIVER R. WULF (U. S. Weather Bureau, CIT, Pasadena, Calif.) *The Diurnal Variation of Irregular Geomagnetic Fluctuations*—The diurnal variation of irregular geomagnetic fluctuations has been studied using the eight daily values of the three-hour-range index K of geomagnetic disturbance for nine years from six observatories in moderately low latitudes and fairly well distributed in longitude. Data for days of different degrees of disturbance have been studied separately. A local-time variation and also a univeral-time variation of disturbance appear to be present. In contrast to the local-time component, the universal-time component exhibits a pronounced annual change. In an attempt to account for characteristics of these components it is suggested that a part of geomagnetic disturbance may arise by dynamo action from air motions in the ionosphere that may be related to the large-scale atmospheric circulation.

J. T. O'BRIEN AND D. I. KUCHENREUTHER (U. S. Naval Civil Engineering Research and Evaluation Laboratory, Port Hueneme, Calif.) *Waves in and around Port Hueneme, California, Associated with the Tsunami of March 9, 1957*—The tsunami, generated by a submarine earthquake off Adak, Alaska (N50.2, W170.7), was noticed first in Port Hueneme and in the ocean near it at 12h 59m Pacific Standard Time, March 9, 1957, and persisted until about 16h PST, March 12, 1957. Simultaneous measurements of wave height were made by means of a bottom pressure pickup in the ocean and a surface float housed in a well in the harbor. Most significant components had periods of about 12.5 minutes and 6.0 minutes with the former magnified considerably in the harbor. An average of 29 hourly readings indicates water level changes of 0.53 ft in ocean and 1.74 ft in harbor, both with half periods of about 6.4 minutes. The magnification in harbor does not seem to be explained on basis of excitation of the harbor or any of its basins; it is speculated that it may be explained by oscillations in the submarine canyon fronting the harbor or sub-harmonic oscillation in the harbor basin. No damage was sustained by Mugu-Hueneme beaches or by Port Hueneme or the ships berthed therein.

GUNNAR I. RODEN (Scripps Institution of Oceanography, La Jolla, Calif.) *On a Relation between Atmospheric Pressure and Sea-Surface Temperature in the North Pacific Ocean*—Nonseasonal pressure and temperature anomalies in the north Pacific Ocean occur on a large scale and cover thousands of nautical miles. There exists a relation between the pressure and temperature anomalies. Changes in the general circulation of the atmosphere are held responsible for a significant part of the variation in sea surface temperatures.

HERBERT B. SCHULTZ (Department of Agricultural Engineering, University of California, Davis, Calif.) *Nocturnal Ground Inversions in Southern California in Winter*—The subsidence inversions in Southern California have been thoroughly analyzed by M. Neilburger and co-workers for the summer months in connection with air pollution problems. The present study of radiosoundings in winter revealed a strong influence of free air subsidence on night temperatures above citrus tree tops. In such conditions, wind machines installed at heights between 30 and 40 ft above ground for winter frost protection are embedded in 10 to 20°F warmer air than the orchards underneath. For a period of 10 years of soundings at Santa Maria, California, and Medford, Oregon, the frequency of the strong subsidence inversions in the lower layers showed a maximum during the winter months followed by a quick decline in the spring. (Similar results were obtained by Herath in a statistical analysis of 25 years of kite soundings at Lindenberg, Germany.) This decline may partly explain the inferior performance of wind machines when used for spring frost protection. Furthermore, the frequent winter subsidence warming over the Southern California citrus areas is magnified by the occurrence of orographic subsidence at night caused by gravity flow. Downslope wind profiles in the Riverside area were observed along a 120-ft mast with sensitive anemometers. Precision recording permitted evaluation of velocity in tenths of a foot per second in time intervals of seconds which showed high variability in time and height. However, the dense foliage of the citrus trees (evergreen) opposes this drainage flow keeping cold air trapped inside the orchard. Therefore, the success of wind machines in winter in Southern California must be ascribed largely to the peculiarity of the combined action of microclimatic and aerological conditions.

GEORGE SHUMWAY (U. S. Navy Electronics Laboratory, San Diego, Calif.) *Acoustic, Geologic, and Physical Properties of a Suite of Arctic Slope Sediments*—Six cores were taken from the continental slope in the Arctic Ocean north of the Coleville River delta in depths ranging from 174 m to 2780 m. As depth increases the sediments become finer and, as the following table shows, a number of other sediment properties change in a regular manner. Sound velocity and attenuation measurements were made by a resonant technique. Static shear strength measurements were made by D. G. Moore with a vane shear apparatus. The cores were collected by M. A. Beal and J. H. Sherman III from USS *Staten Island*.

L. H. STOLZY, L. V. WEEKS, T. E. SZUZSKIEWICZ, AND G. A. CAHOON (Dept. of Irrigation and Soils, University of California, Riverside, Calif.) *Estimating Soil Suction from Neutron Measurements*—Soil water may be evaluated from two different aspects. One aspect commonly reported in hydrology, engineering, and evapotranspiration studies is mass transfer of water. The other aspect common to agronomists and horticulturists is water availability or soil suction. The equipment and methods used to measure each are different. It is often desirable to estimate soil suction from moisture content data. The neutron method is a practical approach to measuring moisture by volume (Pv) in soil profiles. However, in soil profiles moisture per cent cannot be evaluated directly in terms of soil suction. Tensiometers are used to measure soil suction in the field up to 0.8 bar.

It was the purpose of this study to determine soil suction–soil moisture per cent relationships from data taken with tensiometers and neutron equipment under field conditions. These data were also compared to soil suction–soil moisture content data obtained with pressure membrane and pressure plate equipment in the laboratory. Soil suction–soil moisture relationships calculated from data obtained from sandy loam soil packed in large cylinders were not significantly different within cylinders by depths but were different between cylinders. Laboratory determinations of per cent moisture (Pv) at 150 and 330 millibars showed good agreement with the suction-moisture curves from the cylinders. Moisture values measured in the laboratory at 100 and 1000 mb were 23.1 and 8.5 pct respectively. By comparison the ranges of suction values calculated from the cylinder data at the 95 pct confidence interval were as follows: 21 to 23 mb when Pv was 23.1 pct and 540 to 600 mb when Pv was 8.5 pct. Suction-moisture relationships in the field at different locations and depths were significantly different in some cases with the greatest differences occurring at the three-ft depth. Coefficients of correlations for each location and depth varied from −0.95 to −0.99. However, when data from four locations were combined the following correlations were obtained: one-ft depth −0.97 two-ft depth −0.91; and three-ft depth −0.81. This would show that in uniform soil one suction–moisture relationship may represent only a given area. If differences do occur in the profile it may be necessary to make a separate calibration for each depth and location.

RICHARD B. TIBBY (Allan Hancock Foundation, University of Southern California, Los Angeles, Calif.) AND CHARLES G. GUNNERSON (Bureau of Sanitation, City of Los Angeles, Calif.) *Studies on Eddy Diffusion in Santa Monica Bay, California*—Early studies of mixing processes in the sea showed that the coefficient

of horizontal eddy diffusivity was extremely large, that vertical mixing was relatively unimportant, that there was no apparent correlation with net current velocity and that the magnitude of the coefficient varied with the scale of the phenomenon. More recently the view has been expressed that the rate of horizontal diffusion basically is a function of particle separation rather than of time or distance from the source and that the coefficient varies with particle separation according to the 4/3 law. Studies on horizontal eddy diffusion were made in Santa Monica Bay, California, where dye streams, current cross pairs, drift cards and the dispersal of sewage gave values from 1.7×10^2 to 2.0×10^6 cm²/sec for distance scales of 27 m to 20 km. The values approximately followed the 4/3 law and were consistent with those found by other investigators and methods. Engineering applications of these data include the spacing of discharge ports in a submarine sewer outfall prediction of the probable width of the sewage field at its intersection with the shoreline.

Notes and Personalia

Notes

Plans For Extended Abstracting and Indexing Services—A conference was held in Philadelphia, January 29–31, 1958, called by *Biological Abstracts*, under the sponsorship of the National Science Foundation, to consider the needs and problems of abstracting and indexing the world's scientific literature. Representatives of the various abstracting services, such as *Chemical Abstracts*, *Psychological Abstracts*, as well as representatives of fields in which there is now no substantial abstracting service, were present. Six working groups devoted a day to studying individual problems and preparing reports on these problems, following which, at the general sessions, an integrated report was prepared. It was agreed that there should be organized a National Federation of Scientific Abstracting and Indexing Service to integrate the work already in progress and to see to it that the abstract activities are extended appropriately to fields of science not now adequately covered. It was noted that some 500,000 scientific abstracts per year are now covered by the various services, but that there are perhaps on the order of 2,000,000 papers and publications that should be covered. Operating on an extended basis, this endeavor might cost on the order of $20,000,000 a year. In geophysics, it was estimated that there are perhaps 12,000 items per year that should be covered, 3000 of which are now included in *Meterological Abstracts* and about 1000 additional in *Geophysical Abstracts*. Steps have been taken to study this matter on behalf of geophysics by a sub-committee of the Board of Russian Translations, the subcommittee under the chairmanship of Werner A. Baum of Florida State University.

New Publication of the Royal Astronomical Society—The Royal Astronomical Society began the issuance of the *Geophysical Journal*, incorporating the Geophysical Supplement to the Monthly Notices of the R. A. S., Volume 1, Number 1, bearing the date March 1958. It is the plan to publish this as a quarterly. The first number contained nine papers plus a 16-page report on the Eleventh General Assembly of the International Union of Geodesy and Geophysics, held in Toronto, September, 1957. The papers are listed in the bibliography in the current issue of the *Transactions*. There are one falling under a General heading, one under Geodesy, four under Seismology, one in Geomagnetism and Aeronomy, and two in Tectonophysics.

New Publication of the Institute of Physics—*The Physics of Fluids*, under the editorship of François Frenkiel, began publication with the first bimonthly number dated January-February, 1958. This contains seven papers covering various phases of the field.

New Egyptian Publications in Geology—Volume 1, Number 1, of the *Egyptian Journal of Geology*, issued by the Geological Society of Egypt and dated 1957, has recently arrived. The first number contains four papers in English, only one of which, "On the Serial Character of Igneous Rocks," by A. Rittman, bears heavily on geophysics. The Science Council has issued Volume 1 of *Egyptian Reviews of Science*, the first being a review of Egyptian Geology.

New Publication of the British Glaciological Society—Number 1 of *Ice News Bulletin* of the British Glaciological Society dated January, 1958, covers items of current news concerning activities in the study of glaciers and related phenomena.

Ninth Pacific Science Congress—The Ninth Pacific Science Congress, covering the full spectrum of science, was held in Bangkok, Thailand, November 18–December 9, 1957. Five hundred and seventy-five persons attended the Congress. In geophysics, the chief matters of concern related to seismology, meteorology, and oceanography. Further details may be secured from the Pacific Science Association, Bishop Museum, Honolulu 17, Hawaii.

Seventh National Clay Conference—The Seventh National Clay Conference will be held in Washington, D. C., October 20–23, 1958. Interested persons should get into touch with John G. Cady, Program Chairman, Soil Survey Laboratory, Plant Industry Station, U. S. Dept. of Agriculture, Beltsville, Maryland, or H. F. McMurdie, Chairman, at the National Bureau of Standards.

International Oceanographic Congress—This Congress, sponsored by the American Association for the Advancement of Science in connection with the Special Committee on Oceanic Research, ICSU, and UNESCO, will be held at the United Nations Building in New York, August 30–September 12, 1959. Persons who are interested in this matter should get into touch with the Chairman of the Committee on Arrangements, Mary Sears, Woods Hole Oceanographic Institution, Woods Hole, Massachusetts.

Meeting of the Advisory Committee on Arid Zone Research—The Thirteenth Session of the Advisory Committee on Arid Zone Research of UNESCO was held in Karachi, Pakistan, in November, 1957, with E. S. Hills as Chairman for the Session. Forty recommendations were made covering all phases of the Committee's activities from laboratory and field studies to the fellowship program. Attending from the United States was C. W. Thornthwaite, Director, Laboratory of Climatology of Elmer, New Jersey. The Fourteenth Session will be held in Teheran in October, 1958. Interested persons may secure further details by writing to the Committee, c/o UNESCO in Paris.

Immigration of Professional Workers to the United States—Studies of the National Science Foundation indicate that 60,000 immigrants classified as professional, technical, and kindred workers entered the United States on a permanent basis during the four years from July, 1952 to July, 1956, and constitute about six per cent of those immigrating to the United States in those years. Copies of the report can be obtained from the National Science Foundation, Washington 25, D. C.

National Science Foundation Survey of Industrial Research and Development Costs—This survey, which is the third in a series going back to 1953, is sponsored by the National Science Foundation but will in fact be conducted by the Bureau of the Census to compare research and development statistics with other economic data from industrial concerns. Previous studies have indicated that almost three-fourths of the total research and development effort has been provided by industry and that there is good reason to believe that rapid economic growth of some industries has been importantly related to increased investment in research and development.

New Report of the National Science Foundation—The National Science Foundation has recently released a report entitled "Government-University Relationships in Scientific Research and Development." Several recommendations are offered, among these being the need for continuity of support and the need for the Federal agencies to have legal authority to give the institutions title to research equipment procured with the grant or contract funds needed for the work. Copies may be secured from the Superintendent of Documents, Washington 25, D.C., for forty cents.

NATIONAL SCIENCE FOUNDATION FELLOWSHIPS IN SCIENCE FOR 1958–1959—The NSF has announced in March the names of the recipients of 756 predoctoral graduate fellowships for the academic year 1958–1959. These were selected from 3804 applicants. Also announced were the names of 85 winners of regular postdoctoral fellowships (these not including the senior postdoctoral and science-faculty fellowships). Included in the number were 45 in the Earth sciences, 92 in mathematics, 93 in engineering sciences, 158 in chemistry, five in agriculture, and five in astronomy. Of the predoctoral fellowships, 186 were made to first-year graduate students and 196 to terminal-year predoctoral candidate students. The list included 442 who held fellowships during the current academic year. Also announced were about 100 senior postdoctoral and science faculty fellowships.

In April, announcement was made of 525 additional scholarships, 328 in the predoctoral program, 41 in the regular postdoctoral fellowships, 29 senior postdoctoral fellowships, and 127 science faculty fellowships. Details can be secured by writing to the National Science Foundation, Washington 25, D. C.

FELLOWSHIP PROGRAM, ORGANIZATION OF AMERICAN STATES—A new fellowship program will offer grants for advanced study or research to specialists throughout the Western Hemisphere. It is the plan to establish 170 fellowships for the year 1958–1959, with about 500 annually in future years. It is anticipated that grants will be made for periods ranging from three months to two years and will cover such things as travel, fees, work materials, and board and room. Interested persons should address the Technical Secretary, OAS Fellowship Program, Pan American Union, Washington 6, D. C.

NEWSLETTER OF THE INTERNATIONAL ASSOCIATION OF HYDROLOGY—The Association of Hydrology is now publishing a Newsletter distributed without charge to interested persons. This includes activities of the Association as such and also activities of organizations working in related fields as, for example, the World Meteorological Organization. Interested persons should write to Professor L. J. Tison, General Secretary, 61 rue des Ronces, Gentbrugge, Belgium.

DATA REDUCTION OFFICES FOR IGY—The University of Wisconsin and Ohio State University have been given assignments to establish offices to conduct data reduction. The activity at the University of Wisconsin will cover gravity, magnetic, and seismic observations being made by American parties in the Antarctic. The work at the University of Wisconsin will be done under the direction of George P. Woollard. The work at Ohio State will cover glaciological data and will be coordinated with the work of the University of Innsbruck on solar radiation and work at the University of Michigan on ice shelf deformation. The work at Ohio State will be under the direction of Richard Goldthwait.

CONTINUING STATIONS IN THE ANTARCTIC—The Governments of Australia and the United States have agreed to cooperate in maintaining operations at Wilkes Station in the Antarctic for an indefinite period beyond December 31, 1958, the nominal terminal date of the IGY activity. Scientists from both countries will participate in the research activities.

NEW STUDY OF WINDS IN THE UPPER ATMOSPHERE—With the use of rockets which release aluminum chaff more than 50 miles above the Earth, scientists of the Army Signal Engineering Laboratories at Fort Monmouth, New Jersey, are plotting winds in the upper atmosphere. The chaff is released in clouds and is tracked by radar to produce an accurate wind profile as the chaff is swept along by the winds. Continuous measurements have been secured from a height of 283,000 feet down to levels of less than 100,000 feet. Hans J. aufm Kampe and Dudley E. Cline are the ones who are developing this new technique.

GEOTHERMAL POWER DEVELOPMENT IN CALIFORNIA—Work is under way on the first development of geothermal power in the United States. This is in the area of Big Geysers north of Santa Rosa, California, and is being undertaken by the Thermal Power Company.

OCEANOGRAPHIC CRUISE IN THE GULF OF MEXICO, THE CARIBBEAN SEA, AND ADJACENT ATLANTIC WATERS—The Department of Oceanography of the A and M College of Texas has under way an oceanographic survey in areas ranging from Galveston, from which departure took place on May 12, to Bermuda, conducting measurements in temperature, gravity, conductivity, dissolved oxygen, CO_2, chlorinity, alkalinity, phosphorus, and other chemical constituents. Large samples are to be taken from great depths for C-14 determinations.

NUCLEAR REACTOR TO BE USED IN EXPERIMENTS IN ARTIFICIAL PRECIPITATION—The seeding of the steam cloud from Argonne National Laboratory experimental boiling water reactor by silver iodide is being undertaken by a team of scientists under the direction of Roscoe R. Braham, Jr. These experiments are definitely of a laboratory character as compared with the usual field experiments which thus far have been inconclusive. Glass slides with plastic material are placed at various distances downwind and the slides are subsequently examined in the laboratory to see if the ice crystal replicas contain silver iodide particles in the optical center which would indicate that the silver iodide is associated with the nuclear process.

NEW GLACIOLOGICAL MAP OF CANADA—A new map, 63 x 51 inches, has recently been prepared by the Geophysics Laboratory of the University of Toronto and published by the Geological Association of Canada, Room 703, 111 St. Clair Avenue West, Toronto 7, Ontario, Canada. The price is $2.00 (students, $1.00).

GRANT TO IMPROVE INSTRUCTION IN MATHEMATICS IN SECONDARY SCHOOLS—The National Science Foundation has made a grant of $100,000 to Yale University to initiate the work of the School Mathematics Study Group in an effort to improve instruction in mathematics in secondary schools.

WATERSHED MANAGEMENT PROGRAM—The Colorado State University has recently received a grant of $50,000 to aid in the establishment of a full-fledged instruction and research program on watershed management.

NEW COURSE IN GROUND-WATER GEOLOGY—The New Mexico Institute of Mining and Technology announces a program of special graduate courses in ground-water hydrology to start in the academic year 1958–1959. The work will be under the direction of Mahdi S. Hantush, on leave from his post as Dean of the College of Engineering of the University of Baghdad, who has previously devoted six years of study and research as an exchange visitor in the United States. Research facilities are available and a number of assistantships paying $1700 for the academic year will be available. Inquiries should be addressed to E. J. Workman, President, New Mexico Institute of Mining and Technology, Socorro, New Mexico.

TWENTY YEARS OF RESEARCH WORK BY MAGNOLIA PETROLEUM COMPANY—In March, the Magnolia Petroleum Company observed the twentieth birthday of their scientific laboratories, which have expanded from a one-man staff to the present staff of about 380, occupying 25 buildings on a 144-acre tract near Dallas. Over 200 patents on the laboratory's work have been taken out since World War II, and 100 more are pending. Their Marine Sonoprobe, developed by Magnolia and used extensively by Fairchild Aerial Surveys, is used for offshore oil exploration but has also been used to map the bottom of Maine's Passamaquoddy Bay and for other purposes.

Personalia

LESLIE F. BAILEY of the U. S. Coast and Geodetic Survey has received the Meritorious Service Award of the U. S. Coast and Geodetic Survey for his advances in the field of seismology.

GORDON D. CARTWRIGHT, Meteorologist with the U. S. Weather Bureau, has returned after spending 14 months at the Soviet Antarctic IGY station at Mirny in connection with work of the International Geophysical Year. He is the only American stationed at this Russian base and reports that he found the Russian scientists warm, hospitable, and with broad scientific and cultural backgrounds. He took hundreds of cloud photographs and several thousand feet of time-lapse color pictures of special cloud developments.

GILBERT DEWART has recently returned from Wilkes Station in the Antarctic where he spent a year as the station seismologist.

LINDSAY P. DISNEY, Assistant Chief, Tides and Currents Division, U. S. Coast and Geodetic Survey, has been given the Longevity Award for his long years of faithful service in the U. S. Coast and Geodetic Survey.

ALFRED B. FOCKE, formerly the Director of the Marine Physical Laboratory of the University of California at San Diego, has been named Chief Scientist of the U. S. Naval Air Missile Test Center, Point Mugu, California.

JOHN W. GRAHAM, formerly a member of the scientific staff of the Department of Terrestrial Magnetism at the Carnegie Institution of Washington, is now Research Associate in Geology at Woods Hole Oceanographic Institution.

EARL INGERSON, Chief of the Petrology and Geochemistry Branch of the U. S. Geological Survey, has accepted an appointment as Professor of Geology at the University of Texas in September, 1958.

SERGE A. KORFF, Professor of Physics at New York University, has been designated Professor Honorario en Radiacion Cosmica of the Chacaltaya Laboratory of Cosmic Physics of the Universidad Mayor de San Andres in La Paz, Bolivia.

DANIEL LINEHAN, Head of the Geophysics Department at Boston College and Director of the Weston Seismic Station, who has just returned from three months in the Antarctic, has been presented the Insignis Medal of Fordham University. This medal, the award of which honors the zeal of Saint Ignatius of Loyola, founder of the Jesuit Order, is given to Roman Catholic leaders for extraordinary distinction in the service of God through achievement in their professions. A number of years ago he made some extraordinary seismic explorations under Saint Peter's Cathedral in Rome, locating important archaeological finds relating to the early days of the Christian era.

ROBERT R. MCMATH of the McMath-Hulbert Observatory, University of Michigan, has recently been named a member of the National Academy of Sciences.

HOWARD T. ORVILLE, Captain, U. S. Navy, retired, where he was Chief Aerologist, has left his work with the Friez Division of Bendix Aviation Corporation and taken up duties as Vice President of Beckman and Whitley, Inc., San Carlos, California. He will work especially with the Instrument and Missile Products Division in long-range scientific and technical planning.

FRANK PRESS, Professor of Geophysics and Director of the Seismological Laboratory, California Institute of Technology, has recently been elected a member of the National Academy of Sciences.

PAUL A. RECHARD, formerly Director of Water Resources and Commissioner of Interstate Streams for the State of Wyoming, has accepted a position as Senior Engineer for the Upper Colorado River Commission with headquarters in Salt Lake City.

ALFRED C. REDFIELD, Associate Director, Woods Hole Oceanographic Institution, has recently been elected a member of the National Academy of Sciences.

RITA C. SAGALYN of the Air Force Cambridge Research Center was selected to give the Guenter Loeser Memorial Lecture for 1958. The lecture was delivered in the Charter Room of the New England Mutual Building in Boston on June 4. The title of Mrs. Sagalyn's address was "Recent Investigations of Electrical Phenomena in the Atmosphere."

PAUL A. SIPLE, Scientific Advisor and Chief of Research and Development of the Department of the Army, has recently been given the Distinguished Civilian Service Award by the Department of the Army for significant contributions to the scientific knowledge of the Antarctic. He has also recently been awarded the Hubbard Medal, which is the highest honor of the National Geographic Society.

PAUL WEAVER, Professor of Geology at Texas A and M College, has been awarded the Sidney Powers Memorial Medal of the American Association of Petroleum Geologists in recognition of his outstanding contributions to petroleum geology.

WARREN S. WOOSTER has returned to his duties as Associate Research Oceanographer at Scripps Institution of Oceanography after devoting a year as Director of Investigations of the Peruvian Council of Hydrobiological Investigations.

HATTEN S. YODER, JR., Petrologist of the Geophysical Laboratory, Carnegie Institution of Washington, has recently been elected a member of the National Academy of Sciences.

Willis Isbister Milham, Professor Emeritus in Astronomy of Williams College, died March 23, 1957, at the age of 83. He was born at Kinderhook, New York, took his baccalaureate degree from Williams College in 1894 and his master's degree in 1895. He took his doctorate from the University of Strassburg in 1901 and was awarded an honorary doctorate by Williams College in 1946. He entered upon his teaching duties as an Assistant in Physics at Williams College in 1895, and had continued through his career at his alma mater. He became Emeritus Professor in 1942. He had been a member of AGU since 1934.

Peter H. Ottosen, Colonel, U. S. Army, retired, and an associate of the Scripps Institution of Oceanography since 1946, died March 31, 1958, at the age of 72. He was born at Badger, Iowa, and took his baccalaureate degree from Iowa State College in 1908, subsequently doing graduate work at Massachusetts Institute of Technology. From 1908 until 1945, he was a commissioned officer in the Artillery, part of his work being devoted to amphibious training operations. This interested him in oceanographic work. He did research work on the tides and took part in the installation of tide gages at Point Barrow, Alaska, in 1956. He had been a member of AGU since 1946.

Hüseyin Pektas, Head of Fisheries Hydrography of the Fisheries Research Center at the University of Istanbul, died June 11, 1957, at the age of 39. He was born on the island of Cyprus and received his degree from the University of Istanbul in 1940 and his doctorate from Leeds University in England in 1947. He became a member of AGU in 1956.

Union, Section, and Committee Activities

Thirty-Ninth Annual Meeting (1958)

Minutes, General Assembly and Section Meetings

Smoker

The Smoker was held in the Ball Room of the National Press Club, National Press Building, 14th and F Streets, N.W., Washington, D. C., on the evening of Monday, May 5, 1958. There were about 350 in attendance. The gathering was entirely informal and served to provide a pleasant opportunity for those in attendance to greet old friends and meet new ones, and to form ever-changing small discussion groups.

Symposium on Satellite Geophysical Studies

This Symposium was arranged by N. C. Gerson and held in the Great Hall of the National Academy of Sciences on the afternoon of May 6, 1958, John P. Hagen presiding. The session opened at 14h 00m and adjourned at 17n 20m. There were about 275 in attendance. The program, which included discussion from the floor, follows. Abstracts of most of the papers of this and other program papers are to be found in the Reviews and Abstracts of this issue of the *Transactions*.

(1) Lloyd V. Berkner: The IGY and Satellite Vehicles
(2) M. Dubin: Measurements of Meteoritic Impacts on Explorer I
(3) R. A. Minzner: Atmospheric Density from Recent Rocket and Satellite Measurements
(4) G. F. Schilling and T. E. Sterne: Temperatures and Densities Inferred from Observations of USSR Satellites
(5) R. Jastrow and I. Harris: Upper Atmosphere Properties from Minitrack Observations on 1957 α 2
(6) G. W. Swenson, Jr.: Ionosphere Research Using Earth Satellites
(7) H. W. Wells: Ionospheric Focusing at 40 Mc/s
(8) C. Y. Johnson, E. B. Meadows, and J. E. Holmes: Ion Composition of the Arctic Ionosphere

Evening Session

Preceding the Evening Session, there was a subscription dinner at the Statler Hotel in honor of the Bowie Medal recipient attended by about 50 persons including the Minister from The Netherlands, Baron S. G. M. van Voorst tot Voorst, and the Science Attache, J. C. Diels.

The Evening Session was called to order by Vice President L. V. Berkner at 20h 30m, Tuesday, May 6, 1958, in the Lecture Room of the National Academy of Sciences, Washington, D. C. About 200 were in attendance. After appropriate welcoming remarks, Vice President Berkner called on Walter H. Bucher, Chairman of the William Bowie Medal Committee, who cited Johannes Theodoor Thijsse of The Netherlands as the Twentieth Recipient in accordance with the remarks set forth on the opening pages of this issue. Vice President Berkner then made the presentation, and the recipient indicated acceptance in his response, and addressed the assembled group on the subject, In the Borderland between Geophysics and Engineering. At the close of his address a social hour with refreshments was held in the Great Hall of the National Academy of Sciences.

General Assembly: Papers on Frontiers in Geophysics, and Business Meeting

The General Assembly was called to order by Vice President Lloyd V. Berkner at 14h 00m, Wednesday, May 7, 1958, in the Great Hall of the National Academy of Sciences. About 250 were in attendance. Vice President Berkner called on Philip H. Abelson (Chairman, Committee on Meetings, who arranged the program) to act as Chairman and introduce the speakers. The program presented was as follows:

(9) J. A. SIMPSON: Solar-Geophysical Aspects of Cosmic-Radiation Phenomena

(10) FRANCIS BIRCH: Composition of the Crust and Upper Mantle in the Light of Experimental Studies of Wave Velocities in Rocks

(11) ROGER R. REVELLE: The Downwind Expedition to the Southeast Pacific

Upon completion of the session, the chair was returned to Vice President Berkner. Following a brief intermission, the Business Meeting was called to order at 16h 17m.

The minutes of the Business Meeting of the 38th Annual Meeting [see *Trans.*, 38, 438–439, 1957] were approved.

Summary Report of the General Secretary

General Secretary Sayre made a summary report outlining items covered in more detail in the reported minutes of the Executive Committee meetings. He pointed out that during the current year a substantial deficit will occur, caused largely by the greatly increased cost of printing the *Transactions*. Accordingly, the Executive Committee has reluctantly decided that dues for 1959 must be $10.00.

With regard to membership, there are still many qualified persons who are not now members and who should be. The individual assistance of members is needed in bringing these into membership. A directory appears in the April 1957 issue, which should be of help in telling who are members. Application forms appear in the *Transactions* from time to time. We are also seeking more corporation members. A summary of the membership since the last Annual Meeting is as follows:

Membership as of April 25, 1957........	4980	
Reactivated..........................	7	
New members (including 69 applications now being processed)................	503	5490
Resigned	129	
Inactive............................	8	
Dropped (tentatively dropped 148)......	311	
Deceased............................	34	482
Membership as of April 21, 1958....		5008

He noted that the names of 34 members whose deaths had been reported in the last year are cited in the reports of meetings of the Executive Committee and in the brief obituaries carried in the news items in the *Transactions.*

The *Transactions* have been published bimonthly, sometimes a little late. We need more advertising, and the help of members on this is solicited. The Executive Committee, at its meeting May 4, 1958, laid plans for the future development of our publications that will be sent to the entire membership around the late spring or early summer.

Plans have been completed for the publication of Geophysical Monograph No. 2 on the Symposium on the IGY which was held in Washington at the time of the opening of the IGY in July 1957, and tentative plans are under way for the issuance of Geophysical Monograph No. 3 relating to a Conference on Atmospheric Chemistry of the Compounds of Chlorine and Sulphur.

The Russian translation project has been moving slowly. Numbers 1 and 2 of *Izvestiia* (Geophysics Series) have now been released. The quality of translations on these two numbers is only fair, but we have assurance that the quality will be greatly improved. Pergamon Press has promised delivery of the other ten numbers of 1957 by late summer of 1958. Plans are under way to continue this on a more prompt time schedule for 1958. The project for the translation of Russian geophysical abstracts has been dropped.

General Secretary Sayre urged members to watch the minutes of the Executive Committee and Special Announcements in the *Transactions* for detailed word on these and other developments.

Report of the President

Vice President Berkner reported on two things on behalf of President Maurice Ewing, who could not attend the annual meeting because he is recuperating from an operation. The Executive Committee has been doing some detailed planning in order to meet the challenge of the increased quantity of geophysical information that will come from the IGY and from organized activities in geophysics generally. The plan evolved will be referred to the membership for ballot upon the recommendation of the Executive Committee. After careful study by a committee appointed by the President, a report was made, discussed at length, and accepted by the Executive Committee that, commencing with January 1, 1959, there will be issued two journals in the place of one. The first journal, *Research in Geophysics*, will contain only scientific and technological papers and related material, and will be published monthly. It will have page content sufficient to maintain a good balance of all geophysical interests with plans for substantial enlargement as the flow of papers increases. If this proposal is accepted, we must have aid in securing papers from the areas of geophysics that have not heretofore been well represented in the *Transactions*.

The Executive Committee also proposes that the *Transactions* be continued to carry news notes, reviews, and business of the Union, and perhaps descriptive material in the fields of geophysics of broad interest to science teachers. A real effort is being made to increase the advertising. The ballot will come to you for your decision within the next two or three months since it is hoped that final action can be taken and the journals issued on the new basis as of January 1, 1959. The Executive Committee has had a careful study of this in progress for over a year.

A very important Report of the Committee on International Participation will be published in the *Transactions* in August 1958. This brings to a head the discussions that proceeded over many years concerning the relation of AGU to the National Academy of Sciences and to the International Union of Geodesy and Geophysics. The proposal of the Committee was accepted as a basis for discussion at the meeting of the Executive Committee on May 4, 1958. Your comments and opinions are solicited. A change is dictated by urgent necessity. The Executive Committee feels that it is imperative that AGU retain its relationship as the U. S. National Committee of the IUGG since it is felt that the IUGG is the very heart of our work in the use of the Earth as a laboratory.

Reports of Standing Committees

Meetings—Chairman Philip H. Abelson noted that there have been a few departures from our usual meeting plan this year. Previously the Union program mainly consisted of short papers, but obviously when a man has done an exceptional piece of work he deserves a little longer time. The program next year will see something more of the evolution, and since IGY data will be available in great quantity and there will be more analyses, there will be more emphasis on reports from the IGY program. The meeting will be held May 4–6, 1959.

The Pacific Northwest Regional Meeting will be held in Portland, Oregon, November 13–14, 1958.

On behalf of the Union, Vice President Berkner thanked the Committee on Cosmic-Terrestrial Relationships for the arrangment of their symposium before the Section of Geomagnetism and Aeronomy, and N. C. Gerson for arrangement of the Symposium on Satellite Geophysical Studies, and to the many who worked out programs for the Sections. He also noted that the Union owes Chairman Abelson a special vote of thanks for not only arranging the program, Frontiers in Geophysics, but also for all other arrangements for the meeting.

Reports of Special Committees

Resolutions—In the absence of Chairman John N. Atkins, Hatten S. Yoder presented the following resolution which was adopted by the Section of Geodesy:

RESOLVED, That the system of weights and measures in general use in the United States today has been rendered obsolete by nearly world-wide adoption of the metric system, and

That accelerating international communication of technological and scientific data imposes a growing burden of conversion from one system into the other, and

That, therefore, the Congress of the United States should be urged to enact a law abolishing the current system and making compulsory the metric system, this conversion to be initiated immediately by means of education, but not be finally effective for a period of one human generation, or approximately thirty years.

A motion was approved that this matter be referred to a Union committee for study and report.

The following resolutions were then presented which were unanimously adopted:

(1) RESOLUTION TO FURTHER GRAVITY MEASUREMENTS IN THE NORTH ATLANTIC FOR THE PURPOSE OF GEOID DETERMINATION

WHEREAS, The American Geophysical Union, recognizing the discrepancy between the geoid in Europe as given by astrogeodetic methods and that given by gravimetric methods, and recognizing further that these discrepancies might be reconciled by gravimetric studies in the northern portion of the North Atlantic, joins with the Study Group of the International Association of Geodesy charged with the determination of a geoid profile connecting the European and American networks in urging agencies having sea gravity meters to study the area of the North Atlantic, especially the Norwegian Sea, therefore be it

RESOLVED, That a copy of this resolution be sent to the Secretary of Defense.

(2) RESOLUTION OF THANKS FOR THE USE OF FACILITIES

WHEREAS, The success of the Pacific Northwest Regional Meeting at Pullman, Washington, October 29–30, 1957, was due in large part to the space and facilities generously provided by the State College of Washington, therefore be it

RESOLVED, That the thanks of the American Geophysical Union be extended to the State College of Washington for the use of their meeting rooms and other facilities, and that the General Secretary be instructed to forward a copy of this resolution to the appropriate official of the State College of Washington.

(3) RESOLUTION OF THANKS FOR THE USE OF FACILITIES

WHEREAS, The success of the Pacific Southwest Regional Meeting at Pasadena, California, February 6–7, 1958, was due in large part to the space and facilities generously provided by the California Institute of Technology, therefore be it

RESOLVED, That the thanks of the American Geophysical Union be extended to the California Institute of Technology for the use of their meeting rooms and other facilities, and that the General Secretary be instructed to forward a copy of this resolution to the appropriate official of the California Institute of Technology

(4) RESOLUTION OF THANKS FOR THE USE OF FACILITIES

WHEREAS, The District of Columbia Chapter of the American Red Cross has provided the use of its Auditorium for the Thirty-Ninth Annual Meeting of the American Geophysical Union, therefore be it

RESOLVED, That the American Geophysical Union express its great appreciation of this cooperation and instructs the General Secretary to express the thanks of the Union to the appropriate official.

(5) RESOLUTION OF THANKS FOR THE USE OF FACILITIES

WHEREAS, The National Academy of Sciences has provided the use of meeting rooms and other services for the Thirty-Ninth Annual Meeting of the American Geophysical Union, therefore be it

RESOLVED, That the American Geophysical Union express its great appreciation of this cooperation, extended over many years, and instructs the General Secretary to express the thanks of the Union to the appropriate official.

(6) RESOLUTION OF THANKS FOR THE USE OF FACILITIES

WHEREAS, The United States Public Buildings Administration has provided the use of a meeting room and other services for the Thirty-Ninth Annual Meeting of the American Geophysical Union, therefore be it

RESOLVED, That the American Geophysical Union express its great appreciation of this cooperation, extended over many years, and instructs the General Secretary to express the thanks of the Union to the appropriate official.

(7) RESOLUTION OF THANKS FOR THE USE OF FACILITIES

WHEREAS, The Department of the Interior has provided the use of its Auditorium for the Thirty-Ninth Annual Meeting of the American Geophysical Union, therefore be it

RESOLVED, That the American Geophysical Union express its great appreciation of this cooperation and instructs the General Secretary to express the thanks of the Union to the appropriate official.

An informal resolution was also adopted extending the Union's best wishes for good health and speedy recovery to President Ewing.

Adjournment—The meeting adjourned at 16h 44m.

A. NELSON SAYRE, General Secretary
WALDO E. SMITH, Executive Secretary

Appendix A—Minutes of the Annual Meeting of 1958, Section of Geodesy, American Geophysical Union

President Schmidt called the meeting to order in the Auditorium of the D. C. Chapter, American Red Cross, at 09h 15m on May 5, 1958. There was no business to transact except adoption of resolutions which was deferred until the scientific session was completed.

The scientific session proceeded with the reading of the following papers:

(1) FLOYD W. HOUGH: The Role of the Geodesist
(2) C. A. WHITTEN: Distortion in Continental Triangulation
(3) R. K. C. JOHNS: Adjustment of Conditioned Observations with Unknowns
(4) HAL P. DEMUTH: Applications of the Tellurometer
(5) CARL I. ASLAKSON: Geodetic Control in Jungle Areas
(6) IRENE FISCHER: A Tentative World Datum from Geoidal Heights

The session recessed at 11h 35m and reassembled at 14h 00m and proceeded with the following papers:

(7) W. A. HEISKANEN[a] AND U. A. UOTILA: An Accuracy of the Gravimetric N, ξ, and η
(8) W. M. KAULA: A Statistical and Harmonic Analysis of Gravity
(9) J. LAMAR WORZEL: Gravity Measurements on a Surface Ship with the Graf Sea Gravimeter
(10) JOHN A. O'KEEFE: Report of AGU Committee on Geodetic Applications of Artificial Satellites
(11) FREDERICK S. DOYLE: Place for Geodesy in the University Curriculum
(12) J. C. ROSE[a], G. P. WOOLLARD, AND R. M. IVERSON: Gravity Standardization Measurements with the Gulf Pendulums in Australia and New Zealand

[a] Denotes speaker.

Business Session—Two resolutions were submitted and adopted without dissent by the Section to be submitted to the Union (see Union minutes, above) as follows:

(1) A resolution submitted by Finn E. Bronner for adopting the metric system in the United States by means of education and legislation to be finally effective after a period of one human generation, or approximately thirty years.

(2) A resolution submitted by John A. O'Keefe urging agencies with sea gravity meters to study the area of the North Atlantic, especially the Norwegian Sea, in order to reconcile the difference in the determination of the geoid in Europe by astrogeodetic means with the determination by gravimetric methods.

The meeting adjourned at 16h 45m.

FRANK L. CULLEY, Secretary

Appendix B—Minutes of the Annual Meeting of 1958, Section of Seismology, American Geophysical Union

President Benioff opened the Thirty-Ninth Annual Meeting of the Section of Seismology with a brief Business Session at 09h 00m, May 5, 1958, in the Reading Room of the National Academy of Sciences. The minutes of the Thirty-Eighth Annual Meeting of the Section were approved as published [*Trans.*, **38**, 440, 1957]. President Benioff announced the appointment of a committee to arrange for the next meeting to be held jointly, if feasible and mutually agreeable, with the Eastern Section of the Seismological Society of America (L. M. Murphy and Benjamin F. Howell, Jr.). There being no other business, the Business Session was terminated, and the following papers were presented at the Scientific Sessions.

(1) T. GOLD AND D. H. MENZEL: A New Method for Obtaining Seismic Information
(2) R. P. MEYER, J. S. STEINHART, AND G. P. WOOLLARD: Seismic Determination of the Crustal Structure in the Central Plateau of Mexico
(3) DAVID E. WILLIS, ROBERT C. FITZPATRICK, AND J. T. WILSON: Some Observations on the Rainier Underground Nuclear Detonation
(4) LESLIE F. BAILEY AND CARL ROMNEY: Seismic Waves from the Nevada Underground Explosion of September 19, 1957
(5) CARL KISSLINGER: Observations of the De-

velopment of the Surface Wave Pattern in the Vicinity of Small Explosions

(6) A. E. Scheidegger: Tectonophysical Significance of Fault Plane Solutions of Earthquakes in the Northwest Pacific

(7) W. S. Jardetzky: On a Direct Representation of a Disturbance in an Elastic Medium

(8) J. H. Rosenbaum: A Note on the Propagation of a Sound Pulse in a Two-Layer Liquid Medium

After a noon recess, the following papers were presented.

(9) L. Knopoff, J. F. Gilbert, and W. L. Pilant: Pulse Propagation in a Medium with a Single Layer

(10) Howard E. Tatel*, Merle A. Tuve, and Colleagues: Carnegie Seismic Expedition to the Andes, 1957

(11) Frank Press: Velocity Distribution in the Crust

(12) M. Landisman and Y. Sato: Shear Wave Velocities in the Upper Mantle

(13) Jack Oliver and Maurice Ewing: Short-Period Oceanic Surface Waves of the Rayleigh and First Shear Modes

(14) Hugo Benioff and Frank Press: Progress Report on Long-Period Seismograph Recording

(15) N. Blaik, J. Northrop, and C. S. Clay: Some Seismic Profiles Onshore and Offshore Long Island, New York

(16) Walter C. Beckmann, Archie C. Roberts, and Bernard Luskin: Sub-bottom Depth Recorder Survey of Western Long Island Sound

(17) Cecil A. Nanney: A Study of Correlations between Earthquakes and Microseisms

* Deceased November 15, 1957.

James A. Peoples, Jr., Secretary

Appendix C—Minutes of the Annual Meeting of 1958, Section of Meteorology, American Geophysical Union

The Thirty-Ninth Annual Business Meeting of the Section of Meteorology was called to order by President Landsberg at 09h 00m, May 5, 1958, in the Great Hall of the National Academy of Sciences.

As the first item of business, the President obtained approval of the minutes of the Thirty-Eighth Annual Meeting as published [*Trans.*, **38**, 441–443, 1957].

A Resolutions Committee consisting of Chan N. Tuart was appointed, and the announcement of the Nominating Committee appointments was made. The latter consists of Sigmund Fritz, Chairman; Charles L. Hosler, and John C. Freeman.

Conrad Mook, Meteorological Editor for the *Transactions*, then gave a resumé of his editorial activities during the year.

There being no further business, the President adjourned the Business Session at 09h 15m.

The scientific sessions, held jointly with the American Meteorological Society, consisted of the papers listed in the following program.

Monday, May 5, 1958, 09h 00m, Great Hall,
National Academy of Sciences

Meteorology of the High Atmosphere (Richard A. Craig, Chairman)

(1) Paul Julian, William R. Larue, and Hans Panofsky: Estimation of 100-mb Flow from 500-mb Space Smoothed Charts (15 min.)

(2) J. K. Angell: An Analysis of Routine 300-mb Transosonde Flights from Japan (15 min.)

(3) Donald R. Purdy: Some Examples of the Variability of Winds at 300-mb (10 min.)

(4) W. Lawrence Gates: On the Estimation of Vertical Motion at the Tropopause (15 min.)

(5) Edward S. Epstein: The Three-dimensional Field of Motion in the Lower Stratosphere (15 min.)

(6) Sidney Teweles: A Study of Anomalous Warming of the Stratosphere (15 min.)

Monday, May 5, 1958, 14h 00m, Great Hall,
National Academy of Sciences

Symposium—Observational Limitations on the Accuracy of Analysis and Forecasting (Philip D. Thompson, Chairman)

(7) N. E. Laseur: Observational Limitations on the Accuracy of Analysis in Low Latitudes (30 min.)

(8) Charles L. Bristor: The Effect of Data Coverage on Forecast Accuracy (20 min.)

(9) Morton G. Wurtele: A Statistical Assessment of Predictability by Numerical Forecasting (30 min.)

(10) K. R. Johannessen: Some Studies of 'Weather' as an Initial Value Problem (20 min.)

(11) Thomas A. Gleeson: Probability of Observing Specific Phenomena from Network Stations (20 min.)

Tuesday, May 6, 1958, 09h 00m, Lecture Room,
National Academy of Sciences

Statistical Meteorology and Forecasting (Thomas F. Malone, Chairman)

(12) Glenn W. Brier and Isadore Enger: Weather Probabilities Several Months in Advance and Possible Operational Use (15 min.)

(13) R. A. Allen: A Note on Long-Range Prediction (15 min.)

(14) Edward N. Lorenz: Non-Linear versus Linear Objective Weather Predictions (15 min.)

(15) Iver A. Lund, Eugene J. Aubert, and Albert Thomasell, Jr.: Some Six-hour Predictions prepared by Statistical Methods (15 min.)

(16) William C. Spreen and Irving Solomon: An Indirect Method for Estimating the Frequencies of Ceilings Below Various Altitudes and within Various Altitude Ranges (15 min.)

(17) **Irving I. Gringorton**: Equivalent Tail-Wind Errors of Forecast and In-Flight Observation (15 min.)

(18) **Adam Kochanski**: Route Winds for Flights at 300 and 200 mb (15 min.)

Tuesday, May 6, 1958, 09h 00m, Auditorium,
Department of the Interior

Meso- and Micro-Scale Meteorology (Robert D. Fletcher, Chairman)

(19) **Tetsuya Fujita**: Precipitation and Cold-Air Production in Thunderstorm Highs (15 min.)

(20) **Chester W. Newton and Harriet R. Newton**: Interactions between Large Convective Rainstorms and Environmental Wind Field (15 min.)

(21) **W. Smith, I. Kaplan, and B. Herman**: The Life Cycle of the Meso-Systems Associated with the May 7–8, 1956 Severe Storms in Texas (15 min.)

(22) **Morris Tepper**: The Formation of Atmospheric Gravity Waves on an Inversion Surface by the Transit of an Upper-Air Isotach Maximum (15 min.)

(23) **William P. Elliott**: The Area within a Concentration Isopleth for Diffusion of SO_2 from a Continuous Point Source (15 min.)

(24) **R. R. Braham, Jr., E. L. Harrington, and T. E. Hoffer**: Use of Refractive Index Turbulence for Estimating Mechanical Turbulence in the Atmosphere (15 min.)

Tuesday, May 6, 1958, 14h 00m, Auditorium,
Department of the Interior

Meso- and Micro-Scale Meteorology (Morris Tepper, Chairman)

(25) **Tetsuya Fujita**: Analysis of the Fargo Tornado of June 20, 1957 (15 min.)

(26) **Walter H. Hoecker, Jr.**: Comparison of Dimensional and Time-Trend Characteristics of Some Tornadoes and Waterspouts (15 min.)

(27) **Ralph J. Donaldson, Jr.**: Radar Echo Characteristics of Hailstorms and Other Severe Thunderstorms (15 min.)

(28) **Homer W. Hiser**: Anomalous Radar Propagation in South Florida (15 min.)

(29) **David Atlas**: New Evidence of Meteorological 'Angel' Echoes (15 min.)

(30) **A. K. Blackadar**: Frictionally Induced Momentum Oscillations and Motion Patterns in the United States (10 min.)

(31) **L. F. Conover**: Sub-Tropical Clouds as Shown by Time-Lapse Photography (10 min.)

Wednesday, May 7, 1958, 09h 00m, Auditorium,
D.C. Chapter, American Red Cross

General Session (George Cressman, Chairman)

(32) **Jerome Namias**: Improvements in Extended Forecasting Resulting from Employment of Numerical Methods (15 min.)

(33) **Hans A. Panofsky and V. R. K. Rao**: The Relation between Lagrangian and Eulerian Correlation (15 min.)

(34) **L. Machta**: On the Use of Carbon-14 as a Tool in Meteorology (15 min.)

(35) **R. R. Braham, Jr.**: Cloud Duration as an Important Parameter in Cloud Seeding (15 min.)

(36) **Floyd C. Elder and Donald J. Portman**: Some Measurements of the Atmospheric Radiation at Colorado Springs and at the Summit of Pikes Peak (15 min.)

(37) **Robert G. Fleagle**: Comments on Turbulent Transfer at the Sea Surface (15 min.)

Thursday, May 8, 1958, 09h 00m, Lecture Room,
National Academy of Sciences

Physical Meteorology (Ferguson Hall, Chairman)

(38) **Charles L. Hosler**: The Role of Dilute Solutions in Nucleating the Ice Phase (15 min.)

(39) **Gilbert D. Kinzer and W. E. Cobb**: Analysis of the Growth and Collection Efficiency of Cloud Droplets (15 min.)

(40) **W. E. Cobb and Gilbert D. Kinzer**: Laboratory Measurements of the Growth of Cloud Droplets (15 min.)

(41) **Paul A. Allee and B. B. Phillips**: Measured Values of Droplet Charge, Polar Conductivities, and Potential Gradients in Supercooled Orographic Cumuliform Clouds (15 min.)

(42) **B. B. Philips and Gilbert D. Kinzer**: Measurements of the Size and Electrification of Droplets in Cumuliform Clouds (15 min.)

(43) **Bernice Ackerman**: Liquid Water Contents of Tropical Cumuli (15 min.)

(44) **Christian E. Junge**: The Sulfur Budget in the Atmosphere (15 min.)

Thursday, May 8, 1958, 09h 00m, Great Hall,
National Academy of Sciences

Symposium—Tropical Cyclones (Gordon Dunn, Chairman)

(45) **C. L. Jordan**: The Thermal Structure of the Hurricane Core (20 min.)

(46) **N. E. Laseur**: Detailed Low-Level Wind and Pressure Data from Hurricane Edith, 1955 (20 min.)

(47) **R. H. Simpson**: Horizontal Eddies in the Hurricane Circulation (20 min.)

(48) **Harry F. Hawkins**: Hurricane Winds at Flight Levels Related to Low-Level Wind Data (15 min.)

(49) **Robert C. Gentry**: Use of Winds Inside the Strong Vortical Circulation of Hurricanes to Predict Storm Movement (15 min.)

(50) **L. F. Hubert**: Distribution of Surface Friction in Hurricanes (15 min.)

Thursday, May 8, 1958, 14h 00m, Great Hall,
National Academy of Sciences

Tropical Meteorology (Werner A. Baum, Chairman)

(51) **William H. Haggard**: The Birthplace of North Atlantic Tropical Storms (15 min.)

(52) **Emanuel M. Ballenzweig**: Formation of Tropical Storms Related to Anomalies of the Long-Period Mean Circulation (15 min.)

(53) **Robert M. Cunningham**: Details of At-

mospheric Structure in and Around Bahaman Cumulus (15 min.)

(54) **Akira Kasahara**: A Comparison between Geostrophic and Quasi-Nongeostrophic Numerical Forecasts of Hurricane Movement with the Steering Model (15 min.)

(55) **Donald L. Jorgensen**: Predicting Atlantic Coast Hurricanes by Means of Synoptic-Climatological Relationships using Orthogonal Polynomials (15 min.)

(56) **Louis Berkofsky**: Some Preliminary Results of Numerical Hurricane Formation Prediction (15 min.)

Thursday, May 8, 1958, 14h 00m, Lecture Room, National Academy of Sciences

Climatology (Woodrow C. Jacobs, Chairman)

(57) **Isadore Enger**: The Period of Time Required to Determine a Daily Normal (15 min.)

(58) **H. C. S. Thom**: The Distribution of Annual Tropical Storm Frequency (15 min.)

(59) **J. Murray Mitchell, Jr.**: A New Test for Homogeneity of Historical Temperature Records (15 min.)

(60) **Oskar Essenwanger**: Frequency Distribution of Precipitation in a Logarithmic Scale (15 min.)

(61) **Oscar E. Richard**: Comparison of Methods of Computing Degree Days (15 min.)

(62) **J. Murray Mitchell, Jr.**: Effect of Changing Observation Time on Mean Temperature (10 min.)

(63) **John T. McCabe and Thomas D. Potter**: A Method for the Construction of Climatological Fallout Patterns (10 min.) Read by **Lester Machta**.

Woodrow C. Jacobs, Secretary

Appendix D—Minutes of the Annual Meeting of 1958, Section of Geomagnetism and Aeronomy, American Geophysical Union

The Thirty-Ninth Annual Meeting of the Section of Geomagnetism and Aeronomy was called to order at 09h 00m, May 6, 1958, in the Great Hall, National Academy of Sciences, by President Henry R. Joesting. There were approximately 110 members and guests in attendance. The minutes of the 1957 meeting were approved as published [*Trans.*, **38**, 443–444, 1957]. There being no old or new business, the first scientific session was started at once. This session was devoted to a Symposium on Cosmic-Terrestrial Relationships, Walter Orr Roberts acting as Chairman. The following papers were presented:

(1) **Sydney Chapman**: The Terrestrial Implications of Thermal Conduction in the Solar Corona; invited comments: Eugene N. Parker

(2) **Joseph W. Chamberlain**: The Present State of Speculation about the Origin and Acceleration of Aurora-Producing Particles; invited comments: S. F. Singer, Constance Warwick, and R. Jastrow

(3) **John A. Simpson**: What We Have Learned about Planetary Magnetic Fields and the Production of Cosmic Rays from the Flare of February 23, 1956; invited comments: John R. Winckler, Scott E. Forbush, and Dana K. Bailey

The second scientific session was called to order by President Joesting at 09h 00m on May 7 in the Great Hall, National Academy of Sciences, with about 90 members and guests in attendance. The following papers were presented:

(4) **J. D. Stolarik**[a], **I. R. Shapiro, and J. P. Heppner**: The F-ΔD-ΔI Ground Station Magnetometers for Project Vanguard

(5) **C. M. Carmichael**[a], **and R. J. Uffen**: Remanent Magnetization of Some Allard Lake Ilmenites

(6) **R. R. Doell**: Paleomagnetic Interpretations

(7) **S. F. Singer**: Role of Ringcurrent in Magnetic Storms

(8) **Leo R. Davis**[a] **and Otto E. Berg**: Rocket Measurements of the Electron and Ion Fluxes in an Aurora

(9) **E. P. Bialecke**[a] **and A. A. Dougal**: Laboratory Measurements of the Recombination Coefficient of Electrons and Ions in Nitrogen Gas at Very Low Electron Temperatures

(10) **Alfred J. Zmuda**: A Method of Analyzing Values of the Scalar Magnetic Intensity

(11) **John F. McClay and Paul F. Fougere**[a]: Mutually Consistent Spherical Harmonic Analysis

(12) **Kurt Toman**: A Statistical Relationship between Sunspots and M-Regions

(13) **Edwin J. Chernosky**: Geomagnetic H Intensity before and after a Disturbed (5 D) Day

During both of the scientific sessions there was active informal discussion from the floor following the presentation of each paper. The meeting was adjourned at 11h 50m.

R. E. Gebhardt, Secretary

---

[a] Denotes speaker.

Appendix E—Minutes of the Annual Meeting of 1958, Section of Oceanography, American Geophysical Union

President Roger Revelle called the meeting to order at 09h 15m, May 6, 1958, in the Reading Room, National Academy of Sciences. There were approximately 40 members of the Section in attendance.

Since no corrections had been received, or were made from the floor, the minutes of the 1957 meeting were approved as published [*Trans.*, **38**, 444, 1957].

President Revelle announced the appointment of the Nominating Committee, composed of D. E. Carritt, *Chairman*; R. S. Arthur; B. C. Heezen; R. C. Vetter; and W. S. Von Arx.

An announcement was made by President Revelle concerning the proposed International Oceanographic

Congress to be held in early September, 1959, at the United Nations Building, New York.

John Lyman reported to the Section the decisions reached by the Executive Committee of the Union regarding publications, composition of the Executive Committee, and dues.

The Secretary presented a brief statement to the members of the Section regarding the problems associated with the planning of the program for the scientific sessions. Nearly two-thirds of the papers were received after the official closing date for the program.

The Business Meeting was then adjourned and the scientific sessions commenced. Because of the number of late papers, the program as presented and printed herewith differed considerably from that printed in the program.

(1) J. E. CHAPPELEAR: The Calculation of Wave Forces on Groups of Vertical Cylinders
(2) L. E. BORGMAN: An Algorithm for the Ocean Wave Forces on Inclined Cylinders
(3) A. H. SCHOOLEY: Profiles of Wind-Created Water-Waves in the Capillary-Gravity Transition Region
(4) W. J. PIERSON: Linear and Non-Linear Problems in Wave Theory for Waves Influenced by Both Gravity and Surface Tension
(5) R. O. REID: Effect of Coriolis Force on Edge Waves; Part I
(6) K. KAJIURA: Effect of Coriolis Force on Edge Waves, Part II (presented by R. O. Reid)
(7) D. L. ANDERSON[a] AND W. F. WEEKS: A Theoretical Analysis of Sea-Ice Strength
(8) T. S. AUSTIN: Variations with Depth of Oceanographic Properties along the Equator (presented by E. D. Stroup)

Tuesday, May 6, 1958, 14h 00m, Lecture Room, National Academy of Sciences

(9) W. B. BAILEY: On the Dominant Flow in the Strait of Belle Isle
(10) W. H. MUNK AND RICHARD HAUBRICH: The Polar Tide
(11) H. B. STEWART: Net Upstream Flow of Bottom Water in New York Harbor
(12) J. B. SMITH, LELA M. JEFFREY, AND D. W. HOOD[a]: Evidence for the Presence of Carbamino Carboxylic Acids in Sea Water
(13) J. H. CARPENTER: The Solubility of Oxygen in Water
(14) B. J. GILETTI: Circulation Rates of Near-Surface Atlantic Ocean Waters and the Cosmic-Ray Production of Tritium
(15) W. S. BROECKER, K. K. TUREKIAN[a], AND B. C. HEEZEN: The Relation of Deep-Sea Sedimentation Rates to Variations in Climate
(16) I. I. SCHELL: A Reconciliation of an Increased Circulation Characteristic of an Ice Age with a Decrease in Temperature and Solar Radiation

Wednesday, May 7, 1958, 09m 00m, Lecture Room, National Academy of Sciences

(17) J. R. LUMBY: Present Status of the Data Center (A) for Oceanography
(18) W. T. MCGUINNESS AND W. L. DONN[a]: The IGY-Island Observatories: Atlantic
(19) W. L. DONN[a] and W. T. MCGUINNESS: Seiches in Grindavik Harbor, Iceland
(20) L. E. EBER[a] AND O. E. SETTE: Indices of Variations in Strength of Atmospheric Circulation over the Pacific Ocean
(21) B. D. ZETLER[a], H. B. STEWART, AND C. B. TAYLOR: Recent Ocean Temperature and Sea Level Anomalies on the West Coast
(22) M. P. WENNEKENS: Hydrography of the Straits of Florida
(23) D. F. LEIPPER: The Impact on Oceanography of the NAS Meteorology Report
(24) D. F. LEIPPER: Staff and New Facilities in Oceanography at Texas A & M

As a result of questions raised by D. L. Leipper's presentation of the next to last paper, the Executive Secretary of the newly formed Committee on Oceanography of the National Academy of Sciences, R. C. Vetter, outlined some of the activities of the Committee for the assembled members.

DONALD W. PRITCHARD, Secretary

[a] Denotes speaker.

Appendix F—Minutes of the Annual Meeting of 1958, Section of Volcanology, Geochemistry, and Petrology, American Geophysical Union

President Schairer called the meeting to order at 14h 00m, May 5, 1958. No corrections to the minutes of the Annual Meeting of 1957 were received. President Schairer discussed briefly the concern of our Section for broadening the scope of activities of the International Association of Volcanology, the activities of the Eleventh General Assembly of the IUGG, and the plans for the Twelfth General Assembly in Helsinki in 1960. The Nominating Committee, appointed by the President to provide a slate of Section officers to take office after the meeting in 1959, includes W. W. Rubey, Chairman; O. F. Tuttle; and G. R. Tilton. The technical sessions began at 09h 00m, May 5. The program sponsored by our Section was as follows:

Monday, May 5, 1958, 09h 00m, Auditorium, General Services Building

(1) A. W. LAWSON AND JOHN C. JAMIESON[a]: Energy Transfer in the Earth's Mantle
(2) KENNETH O. BENNINGTON: Energy Transfer during Metamorphic Differentiation
(3) ANATOL J. SHNEIDEROV: On the Internal Temperature of the Earth
(4) LEON KNOPOFF AND GORDON J. F. MACDONALD: The Magnetic Field and the Central Core of the Earth
(5) GORDON J. F. MACDONALD AND LEON KNOPOFF: The Chemical Composition of the Outer Core

(6) Robert J. Uffen: On the Origin of Rock Magma

(7) F. W. Dickson: Zone Melting as a Mechanism of Intrusion: A Possible Solution of the Room and Superheat Problems

(8) P. J. Wyllie and O. F. Tuttle: Hydrothermal Experiments on the Melting Temperatures of Shales

(9) P. J. Wyllie: The Fusion of Torridonian Sediments by a Picrite Sill in Soay (The Hebrides)

(10) A. E. Beck and J. M. Beck: On the Measurement of the Thermal Conductivity of Rocks by Observations on a Divided Bar Apparatus

Monday, May 5, 1958, 14h 00m, Auditorium, General Services Building

(11) Adrian F. Richards and James M. Snodgrass: Volcano Acoustics

(12) Robert L. Smith, Irving Friedman, and William D. Long: Welded Tuffs, Experimental I

(13) Irving Friedman and Robert L. Smith: The Hydration of Obsidian Artifacts

(14) Philip M. Orville: Composition of Unzoned Pegmatites in Southern Black Hills, South Dakota

(15) E. H. Roseboom, Jr.[a] and G. Kullerud: The Solidus in the System Cu-Fe-S between 400° and 800°C

(16) Lloyd A. Clark: Phase Relations in the System Fe-As-S

(17) H. J. Van Hook: A Preliminary Report on the System Ag_2S-Bi_2S_3-PbS

(18) W. S. Broecker and A. Walton: C^{14}/C^{12} Ratios in Fresh Water Systems

(19) W. Compston[a] and S. Epstein: A Method for the Preparation of Carbon Dioxide from Water Vapour for Oxygen Isotope Analysis

Tuesday, May 6, 1958, 09h 00m, Auditorium, General Services Building (E. P. Henderson, Chairman)

(20) Paul B. Barton, Jr., and Philip M. Bethke: Approximate Single Ion Activity Coefficients from pH Measurements

(21) Donald W. Groff: A Graphic Approach to Meaningful Radiometry

(22) John W. Winchester: Sodium and Potassium Determination by Neutron Activation

(23) Walter Nichiporuk and Arthur Chodos: Concentration of Vanadium, Chromium, Cobalt, Nickel, and Zinc in the Troilite Phase of Meteorites

(24) E. L. Fireman: A^{39} in the Sikhote-Alin Meteorite and Its A^{39}-A^{38} Age

(25) John H. Hoffman and Alfred O. Nier: Cosmogenic Helium Distribution in Iron Meteorites

(26) O. A. Schaeffer and J. Zähringer: The Rare Gas Contents of Iron Meteorites

(27) Royal R. Marshall and David C. Hess: Lead from Stone Meteorites

(28) Paul W. Gast: Isotopic Abundance of Sr^{87} in the Earth and Meteorites

Tuesday, May 6, 1958, 14h 00m, Auditorium, General Services Building (P. M. Hurley, Chairman)

(29) R. K. Wanless and G. B. Leech: Lead Isotope Studies of the Sullivan and Other Deposits in the East Kootenay District, Southeastern British Columbia

(30) R. D. Russell, R. M. Farquhar, and R. L. Stanton: A Revised Interpretation of the Isotope Ratios of Common Lead

(31) E. J. Catanzaro and P. W. Gast: Isotopic Composition of Lead in Pegmatitic Feldspars

(32) A. Walton and W. S. Broecker: Recent Results on the Ionium Method of Age Determination

(33) Donald S. Miller and J. Laurence Kulp: New Isotope Data and the Colorado Plateau Uranium Mineralizations

(34) G. R. Tilton, G. L. Davis, and G. W. Wetherill: The Age of the Baltimore Gneiss

(35) J. Laurence Kulp and L. E. Long: Chronology of Major Metamorphic Events in Southeastern United States

(36) S. S. Goldich, A. O. Nier, H. W. Krueger[a], and J. H. Hoffman: K-A Dating of Precambrian Iron Formations

(37) S. S. Goldich[a], A. O. Nier, and H. Baadsgaard: Three-fold Division of Precambrian in the Lake Superior Region

This program is one-third greater than that of last year and in spite of the experience of this year's officers the schedule was too strenuous to permit the amount of discussion desired. The larger program again allowed the formation of somewhat more homogeneous sessions which reduce the shuffle between papers to a minimum.

L. Thomas Aldrich, Secretary

[a] Denotes speaker.

Appendix G—Minutes of the Annual Meeting of 1958, Section of Hydrology, American Geophysical Union

Vice-President Harry F. Blaney called the Business Meeting to order at 09h 15m, May 5, 1958, in the Lecture Room, National Academy of Sciences. The Vice-President conveyed President Ray K. Linsley's regrets that he was not able to participate in the meeting. President Linsley currently is in London, England, under a Fulbright Fellowship.

Chairman Blaney introduced J. Th. Thijsse of the Technical University of Delft, The Netherlands, Past-President of International Association of Hydrology and the 1958 recipient of the AGU William Bowie Medal. The Chairman stated that the Section was honored and pleased to have Professor Thijsse attend our meetings. W. G. Hoyt, one of the founder members of the Section of Hydrology, was also introduced.

Secretary Wilson reported on recommendations of the Hydrology Nominating Committee for Section officers for the next triennium. The Nominating Committee consists of H. G. Wilm, Chairman; F. J. Veihmeyer; and Arthur Johnson. The Hydrology Executive Committee approved the following nominations and will request the Nominating Committee to select another candidate for Vice-President to replace the previously selected second candidate who found it necessary to withdraw his name:

For President: Harry F. Blaney
Walter B. Langbein
For Vice-President: William E. Hiatt
(to be named)
For Secretary: Charles C. McDonald
Ralph N. Wilson

The Secretary announced that, upon recommendation of the Hydrology Committee on Awards, the Executive Committee selected the paper, Moisture Movement in Porous Materials under Temperature Gradients by J. R. Philip and D. A. deVries as the best Hydrology paper to appear in the *Transactions* of 1957 and that this paper is to receive the Horton Award for that year. A Certificate of Award will be prepared and forwarded to each author at an early date.

Secretary Wilson reported that C. C. Warnick, Chairman, Hydrology Research Committee on Snow, Ice, and Glaciers, is handling arrangements regarding U.S. participation in the Symposium on Physics of Ice Movement, sponsored by the International Association of Hydrology, IUGG. This Symposium will be held in Chamonix-Mont Blanc, France, September 16–24, 1958. Based on information received by Warnick to date, it appears that approximately ten U.S. papers will be submitted to IAH for the Symposium.

The Secretary announced that IAH is sponsoring a Symposium on Forests and Waters, to be held in Germany in August 1959. It is expected that upon establishment of questions to be considered, the various Hydrology Research Chairmen will invite U.S. individuals to prepare papers on the particular questions. Favorable response to these subsequent requests for papers will be appreciated.

The Business Meeting then adjourned and was followed immediately by the Scientific Sessions which consisted of two sessions on a Symposium on Vegetation and Land-Use Influences and two general sessions. The opening session of the Symposium, under the Chairmanship of Vice-President Blaney, began at 09h 35m and recessed at 12h 10m, with about 110 in attendance. The following scientific program was presented:

(1) H. P. Guy: A Method for Determining Trend of Suspended-Sediment Discharge in Streams
(2) Howard Busch[a] and G. Robert Hall: Land Use Trends of the Brandywine Watershed
(3) Walter Langbein: Basic Hydrologic Data for Upstream Engineering and Land Management
(4) Nedavia Bethlahmy: Logging and Surface Runoff (presented by Bernard Frank)
(5) A. L. Sharp[a], A. E. Gibbs, and W. J. Owen: Problems Involved in Determining the Effects of Land Use and Treatment on Water Yields
(6) H. W. Anderson and R. L. Hobba[a]: Forests and Floods in the Northwest

The second session of the Symposium, under the Chairmanship of Howard L. Cook, began May 5 at 14h 00m in the Lecture Room, National Academy of Sciences. The following program was presented with about 80 members and guests present:

(7) Bernard Zeliner[a] and Carl D. Eklund: Hydrologic Effects of Land Use and Vegetation in the Chestuee and Beech River Watersheds in Tennessee
(8) H. F. Smith: The Effect of Urbanization on Runoff
(9) Marvin D. Hoover: Vegetation and Land-use Effects
(10) L. L. Kelly: Discussion of paper by Hoover
(11) Harry F. Blaney: Consumptive Water Requirements of Vegetative Cover in River Basins
(12) H. V. Peterson: Erosion and Sediment Problems on Western Arid Lands

The first general session was called to order by William C. Ackermann, May 6 at 14h 00m in the Reading Room, National Academy of Sciences. The Chairman acknowledged the presence in the audience of H. G. Wilm, President of the International Association of Hydrology. The session was well attended by approximately 100 members and guests.

(13) A. E. Scheidegger: The Random-Walk Model of Flow through Porous Media
(14) Irvin C. Reigner: Prediction of Streamflow for Single-Watershed Calibration
(15) G. N. Alexander: Return Period Relationships
(16) Harry E. Schwarz: Simulation of a Reservoir System
(17) M. Martinelli, Jr.: Some Hydrologic Features of Alpine Snowfields under Summer Conditions
(18) Donald J. Portman: Conductivity and Length Relationships in Heat-Flow Transducer Performance
(19) H. C. Riggs: Regional Frequency of Low Flows of Streams

The last general meeting was called to order by Walter B. Langbein. This session was opened at 09h 10m, May 7, in the Auditorium, General Services Building, and was attended by about 115 members and guests.

(20) Melvin H. Kleen[a] and William H. Sammons: Agricultural Watershed Influences on Runoff Potential
(21) C. E. Jacob: Salt-Water Encroachment in Inclined Confined Aquifers of Non-Uniform Thickness
(22) H. H. Cooper, Jr.: An Hypothesis Concerning the Dynamic Balance of Fresh Water and Salt Water in a Coastal Aquifer
(23) F. A. Huff[a] and J. C. Neill: Application of Several Statistical Methods to Rainfall Frequency Analysis
(24) D. L. Brakensiek[a] and R. K. Frevert: Estimation of Storm Surface Runoff by Infiltration Theory
(25) Dewey R. Soltow and Richard D. Tarble[a]: The Use of a Radar Beacon in Reporting Precipitation

---

[a] Denotes speaker.

(26) G. E. Harbeck and G. E. Koberg[a]: A Method of Evaluating Effects of a Monomolecular Film in Suppressing Reservoir Evaporation

[a] Denotes speaker.

The meeting adjourned at 16h 45m with comments by the Secretary suggesting that authors promptly submit their papers to AGU for publication and expressing appreciation to the members for so actively supporting the Section meetings by their attendance and lively discussion of many of the papers.

Ralph N. Wilson, Secretary

Appendix H—Minutes of the Annual Meeting of 1958, Section of Tectonophysics, American Geophysical Union

The Business Meeting was called to order by President Hess at 09h 08m on May 7, 1958, in the Reading Room of the National Academy of Sciences. Appointment of a Nominating Committee to consist of Ernst Cloos (Chairman), M. King Hubbert, and L. L. Nettleton was announced. The question was raised whether the Nominating Committee should bring in one or two names for each office for the next election of officers. A large majority of members indicated that they felt one name for each office was appropriate. The technical session began at 09h 12m, and consisted of the following papers.

(1) Robert B. Dewey: Traction at Wave Velocity Discontinuities

(2) Hugh C. Heard: The Brittle to Ductile Transition in Solenhofen Limestone as a Function of Temperature, Confining Pressure, and Interstitial Fluid Pressure

(3) D. T. Griggs[a], F. J. Turner, H. C. Heard, and M. S. Paterson: Recrystallization in Calcite Crystals and Aggregates

(4) John Handin: Effects of Temperature on the Strengths of Some Sedimentary Rocks

(5) Aniruddha De: Observations on the Deformation Lamellae in Quartz of Four Indian Tectonites

(6) William F. Brace: Indentation and Plastic Properties of Certain Geologic Materials

(7) T. P. Thayer: Some Problems Related to Dating Peridotites and Intrusive Serpentinites

(8) Matthew F. Norton and Ross F. Giese, Jr.: The Role of Wrench Faulting in Orogeny

The technical session was completed at 11h 58m. President Hess again asked the members present to indicate whether they felt that one nominee per office was enough. On finding that a majority favored one nominee, he announced that as the By-Laws permitted this, a single slate will be presented at the next election. The meeting adjourned at 12h 00m.

B. F. Howell, Jr., Secretary

[a] Denotes speaker.

Union, Section, and Committee Activities

Pacific Southwest Regional Meeting Held in Pasadena, February 6–7, 1958—The annual meeting of the Pacific Southwest Region was held in Pasadena, February 6–7, 1958, with a total registration of 162, with perhaps about 200 in attendance. Six sessions were held, one a general session, another in oceanography and meteorology, another in meteorology and hydrology, one in oceanography, and two in hydrology. Some 25 papers were presented. A luncheon meeting was held at mid-day on February 6, at which the guest speaker was James F. Bonner, Professor of Biology at California Institute of Technology, who spoke on "World Population and World Food." Beyond the two days of meetings, field trips were held on Saturday, February 8, one from 8:00 until noon on the flood control and water conservation facilities of Los Angeles County, and the second from 8:00 until 3:00 as an excursion to the San Dimas Experimental Forest. In accordance with the By-Laws of the Region, the following are named members of the Committee on Nominations to nominate members for the triennium beginning July 1, 1959: Vito A. Vanoni, Eugene Bollay, Townsend Cromwell, and Robert E. Holzer, representing Hydrology, Meteorology, and Oceanography, which three Sections joined in the meeting in February. Townsend Cromwell has been added to the Committee for the current triennium to represent Oceanography, which was not hitherto represented on the Committee.

The meeting for 1959 is planned to be held at Stanford University, and an invitation is before the group to hold the Regional Meeting at the Scripps Institution of Oceanography in 1960.

Additions to the Membership

February 10, 1957 to April 10, 1958

Aarons, Dr. Jules, Air Force Cambridge Research Center, Bedford, Mass. (*d*) 57

Adler, Mr. Paul G., Graduate House (307A), Massachusetts Inst. of Technology, Cambridge 39, Mass. (*b*) 57 S.M.

Aguilar, Mr. Alonso, Jr., P. O. Box 2133, San Juan, Puerto Rico (*g*) 58

Alverson, Mr. James E., 2005 Hearst St., Berkeley 9, Calif. (*cg*) 56

Ambraseys Mr. Nicols N., Room 222, Dept of Soil Mechanics, Imperial College of Science, London, S.W. 7, England (*beg*) 57

Anderson, Mr. Daniel H., P. O. Box 5, Ashville, N. Y. (*df*) 58 S.M.

Andrews, Mr. Alday B., Oakwood Manor, Apt. 31-B, Evergreen and Hunter Streets, Woodbury, N. J. (*b*) 56 A.M.

Andrews, Mr. Gerald S., Surveys and Mapping Branch, Dept. of Lands and Forests, Victoria, B. C., Canada, (*adeg*) 57

Apell, Mr. Charles A., 558 Rutherford Ave., Trenton, N. J. (*abefgh*) 58

Axenfeld, Mr. Sheldon, Div. of Oceanography, U. S. Navy Hydrographic Office, Washington 25, D. C. (*de*) 58

Special Announcements

Back *Transactions*—AGU always welcomes the receipt of *Transactions* that have served their purpose in the hands of members and offers to pay postage involved in the return of these. Special need arises from time to time for certain ones. At the present time, copies of February, 1957, are especially requested.

Symposium on Snow and Glaciers—The International Association of Hydrology is to have a Symposium entitled "The Physics of Ice Movement," which will be held in Chamonix, France, September 16–24, 1958. Ralph N. Wilson, 3322 Stanford Street, University Hills, Hyattsville, Maryland, Secretary of the Section of Hydrology, AGU, is serving as a clearing house on these matters for U. S. Citizens. Others should get into touch with their respective national committees or with the Secretary of the International Association of Hydrology, L. J. Tison, 61 rue des Ronces, Gentbrugge, Belgium.

Pacific Northwest Regional Meeting to be Held in Portland, Oregon, November 13–14, 1958—The Pacific Northwest Regional group will hold its annual meeting in Portland, Oregon, November 13–14, 1958. Interested persons should get into touch with the present Chairman, Norbert Leupold (P. O. Box 5082, Portland, Oregon), or the Chairman-elect (takes office July 1, 1958) Wilbur D. Simons (U. S. Geological Survey, 207 Federal Building, Tacoma 2, Washington).

Pacific Southwest Regional Meeting—Plans are developing for the Pacific Southwest Regional Meeting to be held most probably at Stanford University, California, in January or February 1959. Interested persons should get into touch with the Chairman of the Regional Committee, Vito A. Vanoni, California Institute of Technology, Pasadena 4, California.

Fortieth Annual Meeting—The Fortieth Annual Meeting of the American Geophysical Union will be held in Washington, D C., in the week following the meeting of the National Academy of Sciences, probably May 4–7, 1959. If the National Academy meeting date is changed, we will adjust our meeting to meet in the week following, as is our usual custom. Watch these Special Announcements for further word.

Twelfth General Assembly, IUGG—The Twelfth General Assembly of the International Union of Geodesy and Geophysics will be held in Helsinki, Finland, July 25 to August 28, 1960. It is not too early to begin to lay your plans to attend this important gathering. Interested persons who are citizens of the United States should get into touch with the office of the American Geophysical Union, 1515 Massachusetts Avenue, N. W., Washington 5, D. C.

NATIONAL ACADEMY OF SCIENCES

Number 11 • May 1958

IGY BULLETIN

A monthly survey by the U. S. National Committee for the International Geophysical Year. Established by and part of the National Academy of Sciences, the Committee is responsible for the U. S. International Geophysical Year program in which several hundred American scientists are participating and many public and private institutions are cooperating.

Blue Glacier Studies

The information on which this report is based was supplied by Phil E. Church, Chairman, Department of Meteorology and Climatology, University of Washington, and Robert P. Sharp, Chairman, Division of Geological Sciences, California Institute of Technology.

Glaciers are among the most sensitive climatic indicators in nature: the snow and ice strata deposited from year to year provide a record of past climates and climatic fluctuations; and annual variations in accumulation and ablation (loss of snow or ice, primarily by melting) and advances and retreats of the ice front constitute keys to past and current climatic trends.

During the IGY, glaciologists and meteorologists of many nations are studying most known ice areas of the world, including both the great ice sheets of Greenland and Antarctica and a large number of valley glaciers from polar to equatorial regions. Ultimately, comparison of data accumulated through these worldwide studies will permit a better understanding of past and present epochal climatic variations. Moreover, implicit in an accurate knowledge of present trends are clues to future climates. The broad aspects of the US-IGY Glaciological Program are outlined in *Bulletin No. 2, August 1957*.

As part of the US-IGY effort to determine the present pattern and magnitude of shrinkage or growth of glaciers in the United States and Alaska, two teams of scientists are studying the Blue Glacier in the Olympic Mountains of Washington (Fig. 1) intensively. The University of Washington has established a permanent field station in the upper (accumulation) area of the glacier, and scientists of the California Institute of Technology are working in the lower (ablation) area of the glacier during the summer.

The University of Washington team is studying the mass budget of the glacier, the balance between the snow and ice accumulated and that lost by melting and erosion. This is primarily a meteorological study. The Caltech group is investigating the three-dimensional geometry of the Blue Glacier, its surface velocity, and the distribution of velocity with depth.

Blue Glacier itself is a small valley glacier

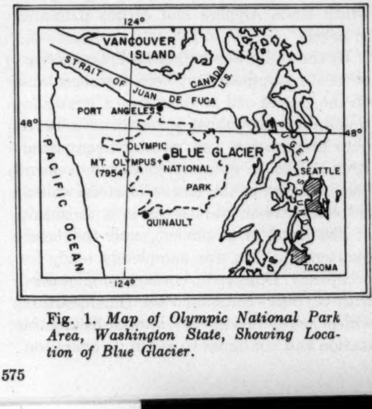

Fig. 1. *Map of Olympic National Park Area, Washington State, Showing Location of Blue Glacier.*

draining from snow fields on the northeast slope of Mount Olympus (47°47′N, 123° 42′W), which lies within the Olympic National Park. It is 2.5 mi long and 0.7 mi in maximum width. Although most of the world's glaciers are retreating at present, Blue Glacier is thought to be growing larger. Most of its accumulation area lies between elevations of about 5900 and 7600 ft above sea level on the 7954-ft mountain.

University of Washington Studies

The University of Washington station is located on a rock outcrop adjacent to the "Snowdome," a domed portion of the accumulation area in the upper part of the glacier, at an elevation of about 6800 ft. This station was established in June 1957. During the next two months a permanent building was erected for use as a headquarters and, nearby, a generator shack, meteorological building, and storage facilities for explosives were also constructed. A "fire cache" was constructed near the camp to hold emergency supplies and equipment to provide shelter in the event of fire or loss through natural disaster. Building materials and supplies were air-dropped by the US Air Force, and scientific equipment was brought in by Air Force and Coast Guard helicopters. The station is also supported by weekly flights of a ski-wheel-equipped light plane which lands supplies and carries personnel in or out.

By the end of September 1957, the meteorological equipment had been installed both on the glacier and at the camp, a triangulation survey to establish a control network for map preparation was virtually completed, 18-ft stakes to measure glacier movement had been set in the cirque (a steep-walled, amphitheatre-shaped recess in a mountain at the head of a glacier), and the headquarters building was completely ready for occupancy. Daily radio contact is maintained with Olympic National Park Headquarters, which cooperated greatly in establishing the station and continues to aid in its operation.

The station was manned by four men from July to September 30, 1957. Beginning on September 1, the winter schedule went into effect: two men remain at the station while the other two work at project headquarters at the University of Washington reducing and analyzing data. The two-man teams alternate each month.

The office work performed at the University of Washington includes reduction of solar radiation data, preparation of a sketch map, and estimate of the 1957 glacier budget. Snow temperature and time profile plots have been worked out for all data collected through the end of December 1957. Some data reduction and survey computations are also done by the field party.

Standard weather observations began in July 1957. The weather data obtained are transmitted daily to Port Angeles by radio. Snow records, obtained daily when weather permits, include amount of snowfall, water equivalent of snow, crystal type, surface densities, and the temperature profile in the surface layers.

Precipitation: Through January 1958, weather records suggest that the wettest part of the continental United States may be on Mount Olympus, near Blue Glacier. It was formerly thought that the Spruce-Quinault area, near the southern border of Olympic National Park, receives the maximum annual precipitation in the United States. However, in the period August through December 1957 there were 61.25 inches of precipitation at Spruce and 45.61 inches at Quinault, while the Blue Glacier Station measured a total of 67.90 inches. Moreover, high winds in November and December may have prevented the rain gauge from recording all the precipitation that fell. The total precipitation through February 1958 was 125.82 inches.

In general, precipitation increased greatly from summer into the fall and winter months—from 5.03 inches in August to 30.44 inches in January. The late fall and winter precipitation fell mostly as snow;

there were 49 inches in November, 118 inches in December, and 120 inches in January. Precipitation was recorded on 24 days in December and 18 days in January. During December, all but one of the 18-ft movement stakes set in the cirque were completely buried. By the end of February the gauges registered 417 inches of new snow; the depth of new snow remaining on the Snowdome was 207 inches.

The liquid water equivalent of the snow falling on Blue Glacier is unusually high. Although falling snow does not generally exceed 10% liquid water equivalent, the snow that fell near the camp in December averaged 25%. An interesting related feature of the new snow during the season at Blue Glacier, samples of which are taken every 24 hours, is its persistently high density. (Generally this was found to be greater than 0.20 gm/cc. Even short-term samples, collected at intervals of one or two hours, have seldom fallen below a density of 0.15 gm/cc.) An important cause of these high densities appears to be the strong predominance of needle crystals (Type 4 of the International Snow Classification) in many snowfalls. The geometry of these crystals can produce snow of high density.

Winds: Wind velocities were generally high and progressively greater, with some fluctuation, throughout the August-through-January period. In September, winds up to 80 mph were recorded on two days. Although it was somewhat less windy in October, so-called damaging winds—winds with velocities greater than 50 mph—were frequent thereafter, occurring on almost half the days during December and January. Winds of more than 100 mph occurred on at least five days in November (some observations were lost because of anemometer failure) and on two days in January; on one occasion, gusts up to 130 mph were recorded.

Temperatures: In August, temperatures averaged 34.9°F. September and October were exceptionally warm months for the Blue Glacier region, averaging 42.3°F and 32.9°F, respectively. During December, temperatures were usually between 20°F and 30°F, with a low of 8°F for the latter half of 1957 occurring in that month.

Snow-Ice Budget: Owing to the abnormally warm weather through early fall, ablation continued during much of October; only six inches of new snow remained on the Snowdome at the end of the month, although 22 inches had fallen.

Although ice-budget studies have been sporadic because of the difficult and time-consuming logistic problems, preliminary results appear to show a slight deficit since last year. This is probably a consequence of light snowfall during the previous winter combined with high summer ablation that persisted longer than usual. Periods of heavy ablation resulted from warm summer storms with high winds. The last of the snow cover accumulated in the 1956–1957 winter season disappeared from the vicinity of the station in early September, whereas about 10 ft of snow had existed at the end of the previous year's ablation period. Snow accumulation in the upper cirque is also lighter than last year's; the maximum observed depth of 1956–1957 winter snow cover remaining in the upper cirque was 16–20 ft in mid-September. Photographic records of new snow-crystal types are obtained whenever a new snowfall occurs.

Movement: It was hoped that it would be possible to resurvey the movement stakes at 15-day intervals to establish the amount and rate of movement of the glacier. This schedule is difficult to keep during the mid-winter months, however, as the number of days on which activity on the glacier is possible is limited by heavy storms, often of blizzard intensity, and by the danger of avalanches along the route to the cirque.

Snow Temperature: A snow settlement gauge is in operation and temperature studies of snow and firn (old snow that has lasted through at least one summer) are proceeding according to schedule. Significant results are being obtained. Winter chill, or sub-freezing temperatures, penetrated to a depth of about 10 ft in the firn by mid-February; the rate of penetration slowed progressively, and greatly, owing to the heavy insulating blanket of new snow.

A probe 50 cm long with thermocouples attached is used to obtain shallow temperatures in the snow and firn; for deeper temperatures, a 50-foot thermocouple cable was sunk into the glacier by hot point drilling. This cable extends to the isothermal layer.

Additional Studies: One new phase of investigation added after the program was under way is an extensive study of snow and ice albedo (percentage of light reflected by the surface), with emphasis on reflected solar radiation measurements made from a light aircraft. If possible, it will be carried out during the summer of 1958. Another, currently in progress when conditions are suitable, consists of time-lapse, photographic studies of cloud formation and development using a 16-mm movie camera. The Snowdome has proven to be an excellent "grandstand" for observing these cloud phenomena. In addition, microbarograph records are being collected for study of passages of fronts, and snow samples are obtained for oxygen isotope analysis at Caltech.

Solar radiation records have been obtained almost continuously but net and total radiation records have been irregular owing to frequent heavy formation of rime (opaque, granular, hard ice that forms on the upwind side of solid objects by freezing of supercooled cloud or fog droplets). This renders the radiometers inoperative for days at a time.

Caltech Studies

The work of the California Institute of Technology team is concerned only with the lower part of the ice stream, from the firn limit (lower limit of the accumulation area) to the terminus. It is hoped that these studies will yield basic information on the geometry and strain rates of Blue Glacier that will permit derivation of a basic flow law for valley glaciers.

The length of this segment of the glacier is 1.1 mi and the width is 0.6 mi. Like the University of Washington field party, the Caltech group received logistic support from the US Air Force and Coast Guard, and is aided materially by the National Park Service. The ski-wheel-equipped light aircraft is also used for resupply.

During the 1957 summer season the Caltech field party spent most of its time setting up experiments that will not yield maximum results until the 1958 season. However, some preliminary results have already been obtained.

Seismic Work: In the summer of 1957, thirty-five seismic stations were occupied on the ice tongue in the lower portion of Blue Glacier. Two of these stations were used solely for refraction and the remainder for reflection studies. A total of 144 records were made, of which two-thirds are expected to yield recognizable reflections.

At most stations the geophones were spread in both transverse and longitudinal orientations with respect to the glacier. Badly crevassed ice almost invariably gave poor results. At some stations no recognizable reflections could be obtained with transverse spreads, whereas excellent reflections were recorded with longitudinal spreads. This suggests that the floor beneath Blue Glacier may be very irregular on a small scale, thus complicating the reflection pattern.

The greatest ice thickness recorded during these seismic studies was about 920 ft, near the center line of the glacier a little below the firn limit. When carefully analyzed, the reflection records obtained along eight transverse profiles across the glacier should provide considerable information on the depth, slope, and configuration of the subglacial rock floor. Data are meager, however, for portions of the glacier near the lateral margins, because of crevasses, thinness of the ice, and complications arising from reflections from the valley walls. Seismic refraction records indicate a wave velocity of 3650 m/sec within the ice.

Movement: To obtain movement profiles, eight transverse lines of stakes were set from just above the lower edge of the glacier to slightly above the firn limit. The stakes, of which 49 were used, were set at an average depth of about 10 ft in the ice. Their positions were determined by theodolite measurements with reference to a system of accurately located fixed points on bedrock and stable moraines along the sides of the glacier. Subsequent resurvey indicates the rate of flow of different parts of the glacier. Preliminary data suggest a maximum velocity along the flow centerline of about six inches per day. Ablation of the ice at these poles was close to 12 inches per week during August 1957, and was uniform over the entire glacier below the firn limit. The stakes will be resurveyed again in the summer of 1958. The resulting data are expected to give the actual flow vector and permit calculation of its various components. Stratigraphic studies of firn were made in two pits, one on the lower glacier and the other on the Snowdome.

Attempts were made to drive boreholes to the bottom at two separate but nearby locations on the glacier. Inclinometer surveys to measure deformation in pipes left in the holes permit construction of vertical profiles of glacier velocity. Neither borehole succeeded in reaching the bottom, but valuable data are expected.

Inclinometer surveys have been made at about 25-ft intervals in both boreholes. Such surveys will be repeated for several years, as long as the holes remain open and unobstructed. One hole, drilled where the ice is thought to be about 900 ft thick, reached a depth of 400 ft. The other, 500 ft up-glacier along the same flow line, reached a depth of 738 ft at a point where the glacier is judged to be 886 ft deep. Drilling became very slow in the deeper hole at about 690 ft, where it is surmised that a band or layer containing much rock debris was entered. Another attempt to drill to the bottom of the glacier will be made in the 1958 field season.

Ice fabrics and structure: Exploratory studies of ice fabrics, the patterns produced by the preferred orientations of ice crystals, were carried out on Blue Glacier during the 1957 field season. The studies had three objectives: a general survey of ice fabrics and their relationship to the easily visible foliation pattern expressed by bubble layers in the glacier ice; a search for possible relationships between ice type and fabric type; study of the lateral persistence and significance of "multiple-maxima-type" fabrics, consisting of numerous clusters of crystals whose optic axes are oriented parallel to one another.

At all localities from which specimens were studied, a well-defined preferred crystal orientation was found. Coarse, recrystallized ice in Blue Glacier apparently has multiple-maxima fabrics, which have also been observed in other glaciers. Multiple-maxima fabrics appear to persist over distances of at least 15 ft laterally, retaining many of their main features. Fine, firn-like ice has fabrics with a well-defined crystal orientation parallel to the c-axes persisting over broader areas. The c-axes lie perpendicular to the plane of foliation.

Structures on the surface of lower Blue Glacier, such as foliation, crevasses, faults, and drag folds, proved to be unexpectedly well-developed and clearly displayed. Of particular interest is a double spoon-shaped structure which appears from beneath the firn and seems to extend to the terminus of the glacier. Detailed mapping and investigation of this and other aspects of Blue Glacier structure are planned by the Caltech group for the 1958 summer season.

Seismic Studies in the Andes

It has been the customary view of geologists that mountains and high plateaus are supported by a substructure of lighter crustal rocks extending downward into the heavier rocks of the earth's mantle, causing mountains to "float" in an isostatic balance, much as icebergs float. Mountains are themselves part of the 30- to 40-km-deep crust of the earth—which is made up of rocks such as lavas, metamorphosed sediments, and granites; these, through long epochs, are subjected to erosion, exposure and reburial, volcanic activity, and percolation of hot, mineralized solutions.

During investigations in the western United States in 1954, members of an expedition conducted by the Carnegie Institution of Washington found strong indications that another kind of substructure may also hold mountains up. A network of relatively narrow roots or veins of lighter crustal rock may project into the earth's mantle, the layer beneath the crust, to depths as great as 200 km. Since these diffuse roots are slightly less dense than the mantle rock, a crown of mountains—or an elevated plateau high above sea level—rises above them to equalize pressures, or maintain "floating equilibrium."

To test this idea elsewhere, the Carnegie Andes Expedition for the IGY during the summer of 1957 undertook investigations of the high regions of Peru, Bolivia, and northern Chile. In this work, they were aided by colleagues from the University of Chile and from San Marcos University in Peru. Their immediate aim was to attempt to determine the character of the roots of the Andes by measuring the waves from explosions used in the great open-pit copper mines of Peru and Chile.

(Compressional elastic waves, such as those generated in the earth by earthquakes or explosions, show a velocity of 5.6–6.1 km/sec in the lighter crustal rocks of the earth. Below the crust, an abrupt transition zone called the M-discontinuity (Mohorovičić discontinuity) is found in most places. Beneath this, in turn, are the heavier rocks of the earth's mantle, in which velocities range from 7.8 to 8.3 km/sec for compressional elastic waves.)

Members of the 1954 Carnegie field party in Arizona, New Mexico, and Utah had discovered that the thickness of the crust—as shown by strong reflections of compressional waves from the upper surface of the mantle—is about the same under the high Colorado Plateau as under the much lower plains and mountains of the eastern United States. This thickness of crustal material, 29 to 34 km, was also found under still higher Alaskan mountains on a 1955 Carnegie Expedition.

Two areas of the globe other than the Colorado Plateau region are characterized by a huge mountain bulk supporting an extensive elevated plateau—the Himalayas in Tibet and the Andes of southern Peru, western Bolivia, and northern Chile. The Andes, where thousands of cubic miles of rock rise to form a tremendous 12,000- to 16,000-ft plateau called the altiplano, were chosen as the site for a continuation of these studies.

In several of the Peruvian and Chilean copper mines single shots of 40 to 60 tons of dynamite are exploded almost every day. These explosions produce elastic waves, especially compressional waves, which pass through the crustal rocks and the higher-velocity rocks of the mantle below the M-discontinuity. It was hoped that observation of these waves, both those travelling along lines parallel to the mountains and those travelling across and beneath the mountains, would provide some clues to the character of the deep-lying structures that support these towering mountains (see Fig. 2).

The expedition, consisting of eight men and six trucks, left Washington in July 1957 and assembled in Lima, Peru, on August 14. During the next three months its members made measurements and recordings at more than 200 carefully selected locations deep in the mountains of Peru, Bolivia, and Chile. Radio timing techniques were used for observing the waves from nearly 60 large explosions. Most of these explosions were at the Toquepala Mine of the Southern Peru Copper Corporation, about 60 miles northwest of Tacna; some were at the Chuquicamata Mine of the Chile Exploration Company, about 125 miles northeast of Antofagasta. Both of these mines are at elevations above 10,000 ft.

Detailed studies of the seismic records have not yet been completed, but the wave measurements indicate that the Andean structures are highly non-uniform. An unexpected difficulty was encountered: the 50-ton explosions were not large enough to permit outlining of the structures deep under the altiplano. Measurements of actual depths to the M-discontinuity by observing strong reflected waves were successful only in limited sectors along lines more or less parallel to the mountains. Suitable observations directly across the mountains were not obtained in spite of weeks of intensive effort.

The reflection waves passing under the altiplano were attenuated to an extreme degree, a situation never encountered in the work in North America. This extreme attenuation may have some connection with the volcanic structures in the Andes, probably indicating that the sharp initial wave pulse is converted to secondary waves at countless interfaces within the mountain structures. Many successive wave conversions then reduce the initial pulse to a long wave train of very low amplitude, which does not show on the instruments above the general unrest of the earth's surface.

By sustained and intensive search, instrument locations were found that were very quiet by comparison with those occupied previously in North America. Although in many places the instruments were capable of detecting vertical wave motions of less than ½ Ångstrom in amplitude (1 Å equals one hundred millionth of a centimeter), no waves were recorded in Bolivia, on the other side of the mountains at distances of 250–450 km from the explosion sites. The amplitude of a normal total reflection in this region would have been expected to reach as much as 600 Å. The reflections observed at comparable distances along the sides of the main bulk of the altiplano, roughly paralleling the mountains, reached amplitudes of 500–800 Å in both Peru and Chile, as might have been expected on the basis of the earlier work in the Rocky Mountains and Alaska.

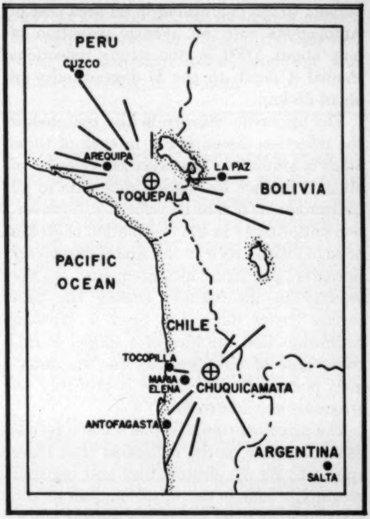

Fig. 2. *Regions in Peru, Chile, and Bolivia Investigated During Carnegie Institute Andes Expedition. Observations of Seismic waves from explosions in mines at Toquepala and Chuquicamata were made approximately along the radial lines.*

In Peru, beneath regions with average elevations of 9,000–10,000 ft, the depth to what appears to be the top of the mantle was found to be about 34 km, approximately the same as under the Rocky Mountains in the United States and Alaska. However, in northern Chile, again along lines roughly parallel to the mountains, in an area east of Antofagasta with an average elevation of only about 5,000 ft, the strong reflections showed a depth to the M-discontinuity of about 55 km.

The apparent velocity in the rock below the reflection discontinuity in each of these areas is similar to the expected velocity of about 8 km/sec for mantle rocks. As in all measurements of mantle velocities, however, non-uniformities in the overburden of 30 km or so of crustal rock in the Andes effectively prevents precision measurements of the velocity in the mantle. During the past several years there has been a growing realization that the idea of a single, world-wide value of wave velocity for the outermost portion of the mantle is probably an erroneous simplification.

The principal result of this seismic reconnaissance, then, is the indication that there appear to be non-uniformities and regional geographic differences in the mantle of the earth, just as there are in the crustal rocks. Under northern Chile, it appears that the lighter rocks of the crust project downward to nearly 55 km. This by itself is enough to float the mass of the Andes overhead. On the other hand, in southern Peru, the crustal rocks extend only to the normal depth of 34 km, and the towering Andes in that area are presumably held aloft by more diffuse roots projecting as much as 200 km into the mantle itself, or at least far below the levels where reflections of the explosion waves could have been observed.

Extensions of these observations of crust and mantle under the Andes may be made in the future by studies of local earthquake waves using a closely-spaced network of special seismographs. Further observations of explosion waves toward the coast are expected to be made during the IGY by the Geophysical Institutes of the University of Chile and of the San Marcos University in Peru using the Carnegie trucks and equipment, most of which were left in South America for this cooperative extension of IGY activity.

Rockoon Flights in the Atlantic, Pacific, and Antarctic Areas

This report is based upon material furnished by James A. Van Allen of the State University of Iowa.

From September 26 to November 9, 1957, thirty-six rockoons (balloon-launched rockets) were launched from the Navy icebreaker USS *Glacier*, as part of the US-IGY program. The first rockoon launching in this series was at 30°N in the Atlantic and the last was at 72°S in the Ross Sea adjacent to Antarctica. James A. Van Allen and Laurence J. Cahill, Jr., of the State University of Iowa (SUI) were in charge of the scientific portions of the program.

This work, together with earlier launchings in the Arctic in August 1957 (described in *Bulletin No. 5, November 1957*), constitutes a unified high-altitude investigation of cosmic-ray, auroral, and geomagnetic phenomena from 75°N to 72°S latitude.

The *Glacier* sailed from Boston on September 23, 1957, passing through the Panama Canal on September 30. It proceeded to the Line Islands area in the central Pacific, then sailed south, entering the Antarctic ice pack on October 31 at about 66°S, 178°W, and penetrating the pack to 72°05′S, 176°30′E.

Launchings were concentrated in the region of the Line Islands in the central Pacific, within the southern auroral zone in the south Pacific, and the Ross Sea. In addition, a series of flights was conducted along the ship's track, and two flights were made off the coast of New Zealand in a cooperative study with the low-frequency ionospheric station of Canterbury University College.

Arrangements for the rockoon-borne experiments were made with US Navy Task Force 43 by the IGY Inter-Service Coordinating Group. Through the courtesy of the Commander Task Force 43 and the Commanding Officer of the *Glacier*, substantial modifications of the sailing plan were made and extensive shipboard facilities and personnel assistance were provided.

Flight Summary

As in the earlier work in the Arctic, the Hawk rockoon vehicle was used (Fig. 3). The rocket was a modified Loki II solid-propellant unit with the experimental apparatus fitted to the forward end in a pointed cylinder, 3 or 3½ inches in diameter and about 38 inches in length. The payload (the weight of the instrument package) varied from 8 to 9.5 pounds. The rocket was suspended on a long load line beneath a 26,000-cubic-foot plastic balloon. It was fired by a barometric pressure switch when the balloon reached an approximate altitude of 23 km. The rockets reached altitudes of about 125 km. A tabulation of flights is given in Table 1.

All balloons performed satisfactorily, although two were damaged during inflation and were discarded. Of the 36 rocket-launching attempts, 20 can be considered normal flights, with summit altitudes ranging from 105–135 km. Seven rockets did not fire; two performed erratically; six were lost owing to equipment failure; and one was lost at launching, in a squall.

Objectives and Results

A major purpose of the rockoon program is measurement of total cosmic ray intensity over a wide range of geographic and geomagnetic latitudes during the present period of high solar activity. Special points of interest are (i) comparison of the intensity at upper atmosphere levels in high southern latitudes with intensity at high northern latitudes, and (ii) investigation of the location of the latitude "knee" (the geomagnetic latitude at which the number of incoming particles appears to fall off sharply) in the southern hemisphere.

Satisfactory cosmic ray intensity measurements up to an altitude of 23 km were obtained in a total of 15 flights distributed along the ship's track from 25°N to 72°S. On four flights (Nos. 52, 76, 84, and 85) satisfactory intensity data at upper atmosphere levels were obtained. These flights were made in many latitudes, but a variety of equipment failures caused a gap in the measurements in the vicinity of 30°S.

By January 1958, five sets of flight data had been read and reduced. They indicate that the total cosmic ray intensity at upper atmosphere levels in high southern latitudes is within 5% of that in high northern latitudes, and about 4.3 times as great as that near the equator. They also show that during the present period of high solar activity the

latitude knee is found at a latitude lower than 50°S. Cosmic ray intensity at various altitudes is being systematically plotted against geomagnetic latitude.

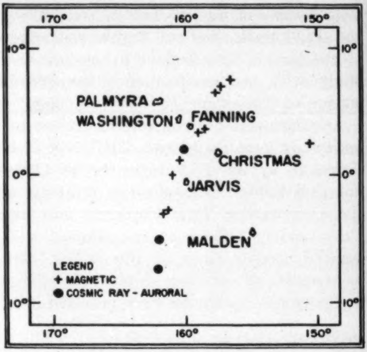

Fig. 4. *Line Islands Area, Showing Locations of Rockoon Flights.*

Another aim of the program was precise measurement of the intensity of the terrestrial magnetic field to altitudes over 120 km in the region of the equatorial electrojet. For these studies, a miniaturized proton precession magnetometer, designed at the State University of Iowa, was used. A detailed comparison of these data with simultaneous measurements made independently with variometers at the nearby IGY magnetic observatories on Palmyra, Fanning, and Jarvis Islands, in the Line Islands group, will be made. (These island observatories are operated by the Scripps Institution of Oceanography for the US Coast and Geodetic Survey and the Office of Naval Research.) Special interest was attached to the detection and measurement of electrical currents in the ionosphere by means of devices extending outward from the sides of the rocket. Such devices permit direct contact with the surrounding atmosphere.

Four satisfactory sets of data on magnetic intensity were obtained in the Line Islands area (Fig. 4) at altitudes up to 135 km (flights 54, 59, 62, and 63). On a fifth flight (No. 64), the magnetometer operated properly but the rocket's peak altitude was less than 70 km.

These flights were made on an approximate north-south line crossing the latitudes of the equatorial electrojet. The two sets of data which have so far been read indicate an

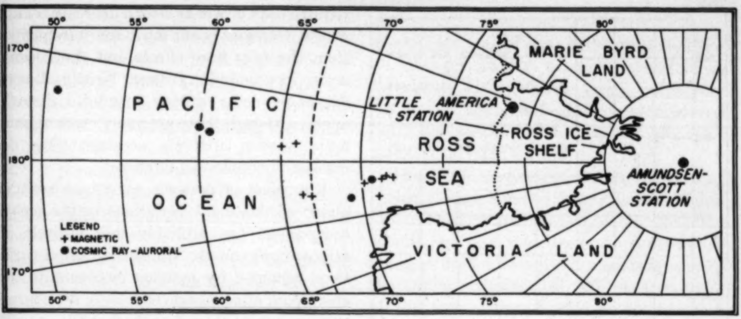

Fig. 5. *South Pacific and Ross Sea Areas, Showing Locations of Rockoon Flights.*

irregular, larger-than-normal decrease of 135 gammas in the total magnetic intensity, within the altitude range 97–121 km at 0° latitude. The absolute accuracy of each of a large number of measurements in this region is +5 gammas. Up- and down-leg data agree closely.

The data from flight 59, at 3°23′N, show a perceptible but markedly smaller discontinuity. The full reduction of all four sets of flight data obtained in the Line Islands area, when combined with the ground station measurements, are expected to yield illuminating information on the equatorial electrojet.

Several other experiments were conducted in the southern auroral zone. High-altitude measurements of the magnetic field were made for correlation with nearby Antarctic observations (Fig. 5). There were three successful magnetometer flights (Nos. 77, 82, and 83). Flight data have not yet been reduced. Investigations were made here of the physical nature, intensity, and latitude distribution of the "soft radiation" associated with auroras. Flight 76 (70°48′S, 175°50′E) was the only successful rocket flight of auroral instrumentation made in the zone. It encountered a high intensity of soft radiation resembling that studied extensively in the northern auroral zone during SUI rockoon expeditions from 1953 to 1957.

Precise absolute measurements of the intensity of the terrestrial magnetic field at sea level were taken at a number of new locations. Two new series of absolute values were obtained. The first series, in the Line Islands area, showed the current magnetic chart, No. 1703 of the US Hydrographic Office, to be correct within the limits of accuracy indicated. The second series of measurements, made in the Ross Sea, showed Chart No. 1703S, which was based on limited data, to be substantially in error in that region. The new values will be published shortly.

Variations in Cosmic-Ray Intensity

Observations of cosmic ray intensity at the earth's surface have long revealed many variations, both periodic and non-periodic. As noted in the report, "Thule Neutron Monitor Station," in *Bulletin No. 8, February 1958*, the intensity of the meson (heavy particle) component of cosmic radiation depends in a very complicated manner on the

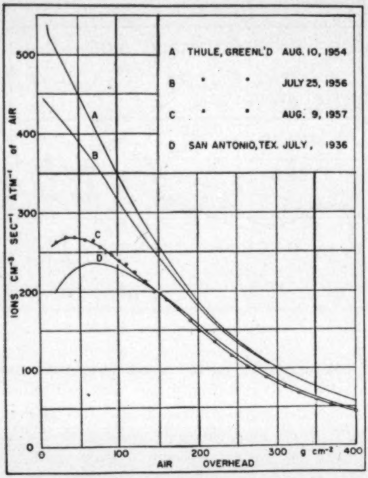

Fig. 6. *Cosmic-Ray Intensities in 1954 and 1956, Years of Low Solar Activity, Compared with Intensities in 1936 and 1957, When Solar Activity Was High. (Reprinted from* Physical Review.)

structure of the ever-changing atmosphere. A number of other intensity variations in both time and space are also observed. Some of these may give clues to the processes which produce and affect cosmic rays.

The largest of the observed variations in cosmic ray intensity are the rare increases associated with solar flares. At these times, neutron-monitor count rates may increase twenty-fold for a short period of time. Such flares have only been observed some half-dozen times.

Another non-periodic variation is the Forbush type of world-wide intensity decrease which occurs in association with some geomagnetic storms. In the Forbush-type decrease the cosmic ray intensity measured in ionization chambers may fall as much as 12% from the "normal" level. In neutron monitors the decrease may be as large as 2½ times this value, depending on the latitude of the station. Recovery to normal level may require days or weeks after a decrease occurs. These decreases occur much more frequently than the solar flare effects, but they do not occur in a periodic pattern. Nearly all such decreases occur during magnetic disturbances, although there are many cases of magnetic storms without accompanying decreases in cosmic ray intensity.

A number of periodic variations are also observed. Seasonal variations in the meson component are probably due entirely to atmospheric causes. The solar diurnal variations recorded by neutron monitors do not arise from atmospheric effects. A semidurnal variation is attributed to the fact that cosmic ray intensity is not the same in all directions.

During the very infrequent solar-flare increases, the variation in intensity may be as great as 25 times the level normally recorded. The decrease in intensity associated with geomagnetic storms may, as has been indicated, amount to as much as 30%. The solar diurnal variation has an amplitude of only 0.2%.

With the exception of the solar-flare increases, cosmic ray intensity variations at surface level are moderate. But investigations made prior to the IGY by H. V. Neher, of the California Institute of Technology, demonstrated that large changes do occur in the primary radiation arriving at the top of the atmosphere, especially in the north polar region. Over a period of years, Neher made observations near the north geomagnetic pole using ionization chambers carried by sounding balloons. His observations show that when the solar activity, as indicated by sunspot numbers, reaches a maximum in the eleven-year cycle the cosmic ray intensity decreases. This was also shown by results from the Carnegie Institution ionization chambers.

Near the north geomagnetic pole the flux of primary particles increased two-and-a-half times from the solar activity maximum of 1937 to the solar activity minimum of 1954. Most of this change was in protons at very low cosmic ray energies, below 10^9 electron volts.

This work has been continued in the IGY with balloon flights made during the summer of 1957 at Thule, Greenland. Figure 6 illustrates the large change that took place as solar activity increased during the cycle. Ionization due to cosmic rays at Thule during this period is reported by Neher and H. Anderson to be nearly 30% lower than during the solar maximum in 1937. They note that this is consistent with the higher level of solar activity during this cycle compared with the cycle of 20 years ago. In Figure 6, the rise of curve C above curve D at low pressures shows that more low-energy particles are present at high altitudes. Comparison of the results at Thule for the solar minimum of 1954 with those of August 1957 (near a maximum of activity) indicates that the total number of cosmic ray particles of all energies dropped by a factor of 4 in that period.

Observation of another variation during the IGY has been made with balloon-borne quadruple-coincidence counter trains launched at Swarthmore, Pennsylvania, under the supervision of M. A. Pomerantz, S. P. Agarwal, and V. R. Potnis, of the Bartol Research Foundation, for the purpose of detecting primary cosmic rays. When such flights were conducted during the period of general decrease of solar activity, 1949–1952, no changes in the primary intensity—as measured with counter trains containing 7.5 cm of interposed lead—were observed (with the exception of the rare increases associated with solar flares).

This is no longer true during the present period of high solar activity. Balloon flights (July–October 1957) have shown that the cosmic ray flux sometimes decreases by as much as 25% below the normal intensity of the earlier experiments. Within the limits of the apparatus, no changes in counting rate were detectable at altitudes below 60,000 feet, but at the highest altitudes attained the intensity varied between the earlier "normal" value and the minimum value.

From preliminary analysis of the data, a 27-day recurring variation has been observed. It has been followed through four cycles. Presumably, this effect is associated with a solar phenomenon which modulates the primary cosmic ray flux and is related to the 27-day solar rotation period. Surface level variations with similar dependence upon the 27-day solar cycle have been established in the past, but were of greatly reduced amplitude.

Second and Third US-IGY Satellites

1958 Beta

The second US-IGY satellite, 1958β, was launched from Cape Canaveral, Florida, at 7:16 am EST on March 17, 1958, under the direction of the Naval Research Laboratory.

Launching: The launching vehicle was a three-stage rocket, the third three-stage rocket fired in the Project Vanguard test program. The first and second stages were liquid-fueled rockets, the third stage a solid-propellant rocket. The first and second stages were stabilized and steered by altering the direction of thrust of the rocket motors. The third stage was stabilized by spinning the rocket about its longitudinal axis prior to ignition of the third-stage motor, thus integrating and cancelling out directional errors. The launching vehicle is approximately 72 feet long and 45 inches in diameter at its base. It is finless and has a gross take-off weight of 22,600 lbs.

Satellite Characteristics: The satellite, actually a test "payload," is an aluminum sphere, 6.4 inches in diameter and weighing about 3¼ lbs. It carries two radio transmitters and has six antennas (Fig. 7).

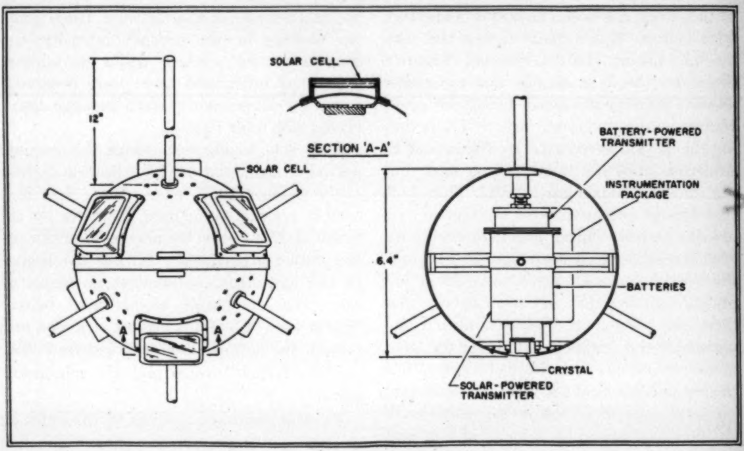

Fig. 7. Diagram of 1958β.

Instrumentation: Since the purpose of the test payload was to provide radio signals by which the rate of acceleration of the third stage could be determined and the efficiency of the separation mechanism checked, the test satellite carried no instrumentation other than the two radio transmitters. One transmitter, radiating 10 milliwatts at 108.00 megacycles, is powered by mercury batteries. This transmitter, which was expected to have a life of approximately two weeks, ceased operating on April 5th. The other, radiating 5 mw at 108.03 mc, is powered by solar batteries which have an indefinite life.

The frequency of each transmitter is controlled by a quartz crystal. Since changes in crystal temperature will cause changes in the frequency transmitted, temperatures at the crystal locations can be computed by measuring the changes in transmitter frequency. The crystal for the solar-powered transmitter is located just beneath the skin of the satellite; the crystal of the other transmitter is at the center of the satellite. Therefore, temperatures at these locations can be measured whenever the transmitters are in operation.

The solar batteries used were developed at the US Army Signal Engineering Laboratories at Fort Monmouth, N. J., under the direction of Hans K. Ziegler. They are a development of a solar battery first produced by Bell Telephone Laboratories in 1954.

Each battery consists of a series of 18 silicon cells, 1/400th of an inch thick; each cell contains two layers of silicon of differing electrical properties. When sunlight strikes a cell, electrons move from the positive layer (p-type) to the negative layer (n-type). The power thus made available to the 108.03 mc transmitter is approximately 40 mw.

Six solar batteries are spaced on the surface of the satellite so that at least one of the batteries will be in direct sunlight unless the satellite is in the earth's shadow. Because of the distance of the satellite from the earth, the satellite is expected to be in shadow only 15% of the time.

Orbit: The orbital elements for March 17 at 13 hrs 58 min 11 sec UT (the time of the first ascending node), as computed by the

Vanguard Control Center on March 18, were:

Period, 134.0 minutes; apogee, 2466 statute miles; perigee, 404 statute miles; inclination of the orbit, 34.1°; longitude of ascending node, 129.2°E; westward geographic motion of the node, 33.89° per day; latitude of perigee on descending branch, 26.1°N; eccentricity of orbit, 0.191; semimajor axis, 1.362.

Observations: Radio signals were received from the satellite on each pass until the battery-powered transmitter ceased operation. Since then, signals have been received only when the satellite is in sunlight.

The first sighting of 1958β was by a Moonwatch team at Alamogordo, New Mexico, on the morning of March 19.

1958 Gamma

The third US-IGY satellite, 1958γ, was launched from Cape Canaveral, Florida, at 12:38 pm EST, March 26, 1958, by a Jupiter-C rocket developed jointly by the US Army Ballistic Missile Agency and the California Institute of Technology Jet Propulsion Laboratory.

Satellite Characteristics: The satellite has essentially the same physical characteristics as 1958α (see *Bulletin No. 10, April 1958*), but does not carry a turnstile antenna with its four whip-like extensions. It weighs 31.00 pounds; this is 0.20 pounds heavier than 1958α.

Instrumentation: As in 1958α, the cosmic ray experiments carried in 1958γ were designed and installed by the Physics Department of the State University of Iowa (SUI) under the direction of James A. Van Allen. The micrometeorite experiments carried in both 1958α and 1958γ were designed and installed by the Geophysics Research Directorate of the Air Force Cambridge Research Center.

The instrumentation of 1958γ is slightly different from that in 1958α. The differences are: addition of a magnetic tape-recorder unit, designed by G. H. Ludwig of SUI, to record and store information on cosmic rays gathered through an entire orbit; addition of a radio to receive interrogation signals from ground stations; omission of the microphone for recording of micrometeoritic impacts on the satellite shell; omission of the temperature probe in the nose cone; and use of a dipole antenna, formed by dividing the shell of the satellite itself, in place of the turnstile antenna.

Fig. 8. *Magnetic Tape Recorder Used in 1958γ to Record Information and Transmit it to Ground Stations When Interrogated.*

1958γ carries two transmitters, identical to those in 1958α. The low-power transmitter, operating on 108.00 mc, transmits information continuously on skin temperature and internal temperature, micrometeorite counts as recorded by an erosion grid, and cosmic ray counts. The high-power transmitter, operating on 108.03 mc, transmits only when interrogated by a ground station, and sends only cosmic ray information recorded in the tape recorder memory unit (Fig. 8). It is interrogated each time it passes over the Minitrack network along the 75th meridian in North and South America. The signal from the ground station is picked up by a receiver; this starts the magnetic tape running over the playback head and at the same time switches on the high-power transmitter. In five seconds the results of up to two hours of cosmic ray observations are sent to the ground station. The magnetic tape is automatically erased and the recorder reset to record data during the next orbit. By using this interrogation technique the life of the high-power transmitter is expected to be extended to two months or more.

Orbit: Because the third stage fired early, before it had reached proper alignment, the orbit of 1958γ is more elliptical than that of any of the IGY satellites fired earlier. The approximate orbit as of March 28 was: Period, 115.9 minutes; inclination of orbit to the equator, 33.8°; perigee, 116.9 miles; and apogee, 1740.8 miles. This somewhat eccentric orbit is providing a scientific bonus for it gives a sweeping profile of cosmic ray information from relatively low to quite high altitudes.

IGY News from Other Countries

New Zealand Antarctic Symposium

Scientists of seven nations met in Wellington, New Zealand, February 18–22, 1958, at the invitation of the New Zealand National Committee for the IGY, to take part in an informal discussion of IGY work accomplished in the Antarctic during the preceding year. Nations represented in addition to New Zealand were Australia, France, Great Britain, South Africa, the USA, and the USSR. Two types of meetings were held: those of general interest at which informal papers were presented and discussed, and round-table discussions among delegates concerned with a particular discipline.

A list of symposium discussions, together with the chairmen of each, follows: Special Investigations in Glaciology, J. L. Zumberge, US; The Topography of the Sub-Glacial Continent, Bertrand Imbert, France; Geomagnetism, R. L. Viets, US; Logistic Support Problems in the Antarctic, M. A. F. Barnett, NZ; Meteorology, V. I. Rastorguev, USSR; Seismology, T. Hatherton, NZ; Biology, Botany, and Zoology, R. W. Balham, NZ; Oceanography, U. V. Cassie, NZ; Aurora, F. Jacka, Australia; Geology, R. W. Willett, NZ; Radiation and Micrometeorology, Herfried Hoinkes, US; and Future Research in the Antarctic, G. de Q. Robin, Great Britain.

Most of the delegates had just returned from the Antarctic and had not had the opportunity to prepare formal papers. The symposium permitted exchange of field results and discussion of items of interest affecting future work without the need to wait for publication of papers.

Participants in the symposium are now preparing papers covering the subjects discussed. These papers will be published by the New Zealand National Committee for the IGY in the near future.

IGY BULLETIN

A monthly survey by the U. S. National Committee for the International Geophysical Year. Established by and part of the National Academy of Sciences, the Committee is responsible for the U. S. International Geophysical Year program in which several hundred American scientists are participating and many public and private institutions are cooperating.

Total Solar Eclipse: October 12, 1958

Since 1836 scientists have been making physical observations of the solar spectrum during eclipses, especially of the spectrum of the corona, the outer atmosphere of the sun (see Fig. 1). Invention of the coronagraph by Lyot in 1930 made it possible to observe some aspects of the corona without waiting for an eclipse; but the "artificial eclipse" of the coronagraph does not completely eliminate the scattered light from the sun's disk. In a total eclipse, radiation from the solar disk is blocked by the moon; for a short period, therefore, only radiation from the corona reaches an observer in the path of totality. Thus, an actual solar eclipse provides a unique opportunity to study characteristics of the sun and of solar-terrestrial relationships which cannot be duplicated in a laboratory.

Studies of the distribution of different radiation wavelengths on the sun's disk and the effects of specific wavelengths on the ionosphere are made possible during an eclipse since the moon acts as a shutter, successively blocking off portions of the disk. This effect cannot be duplicated by the coronagraph.

The total eclipse of the sun due on October 12, 1958, occurs at an extremely opportune time for solar studies; the solar physics studies of the IGY will provide an abundance of data on the sun for long periods before and after the eclipse. It also occurs near a period of maximum solar activity, the most active solar maximum in recorded history. September and October 1957, on the basis of preliminary reports, had the highest sunspot numbers ever recorded. At the time of the eclipse the sun should still be very active.

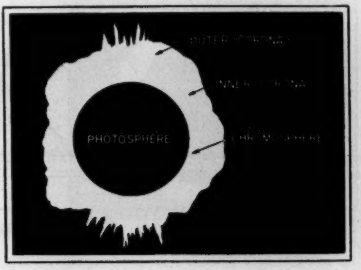

Fig. 1. *Solar Regions. The visible disk of the sun is called the* photosphere (*sphere of light*). *Above the photosphere is the* chromosphere (*sphere of color*). *The portion of the chromosphere immediately above the photosphere is sometimes called the "reversing layer." Above the chromosphere is the* corona (*crown*), *which is divided into* inner corona *and* outer corona, *or* white corona. *The boundaries between regions are not definite, one region merging imperceptibly into another.*

Observational Program: The Technical Panel on Solar Activity of the US National Committee for the IGY is taking full advantage of this favorable situation and has organized an extremely broad observational program. Six teams of US scientists will travel

to the Danger Islands, an atoll in the South Pacific also known as Pukapuka after the largest island in the group; there they will mount four ground-based optical experiments, one rocket experiment, and one ground-based electronic experiment. Preparations for these experiments have been underway since before the beginning of the IGY in July 1957.

Existing weather records indicate a 40% chance that clouds will obscure the sun during the critical period of totality, but cloud conditions will impede only the optical experiments. No matter what the weather, the electronic experiment and the rocket observations will go forward and should obtain extremely valuable data on solar radiation and associated ionospheric effects.

The institutions participating in the expedition are the Naval Research Laboratory (NRL), the Central Radio Propagation Laboratory (CRPL) of the National Bureau of Standards, the University of Wisconsin, the California Academy of Sciences, the US Naval Radiological Defense Laboratory, the Sacramento Peak Observatory, and the High Altitude Observatory.

Logistic Problems: The main problem facing the planners of the expedition has been the selection of a suitable piece of land on which to erect the observational instruments. The path of totality begins at sunrise approximately on the equator at about 158°E and ends at sunset at a point inland from Santiago, Chile (see Fig. 2). The path misses all the large Pacific Islands, and observations from Chile would be impractical because of the low altitude of the sun at the time of eclipse. The only dry land from which observations would be profitable are coral islands too small to support a large expedition comfortably.

The logistic problem has been solved with the help of the Navy, which is furnishing the USS *Thomaston*, a Landing Ship Dock (LSD), to serve as transportation, floating hotel, and warehouse for the period the expedition is at the Danger Islands site. The expedition plans to arrive at the Danger Islands about September 1 and leave on November 1. Except for a period of one week during which the *Thomaston* will travel to Samoa to refuel, all personnel will live aboard the ship. They will be ferried by boat and helicopter to and from the observational site on the most southerly island of the group, Motu Koe.

Since the *Thomaston* is much too large to enter the lagoon of the atoll by the only passage, and anchorage is not possible outside the atoll, the LSD must steam back and forth in the open ocean two or three miles from the outer reefs to maintain position.

Electronic Experiments

Two electronic experiments, one by the Naval Research Laboratory and one by the CRPL, National Bureau of Standards, will observe ionizing sources on the sun and the resultant ionization in the earth's atmosphere.

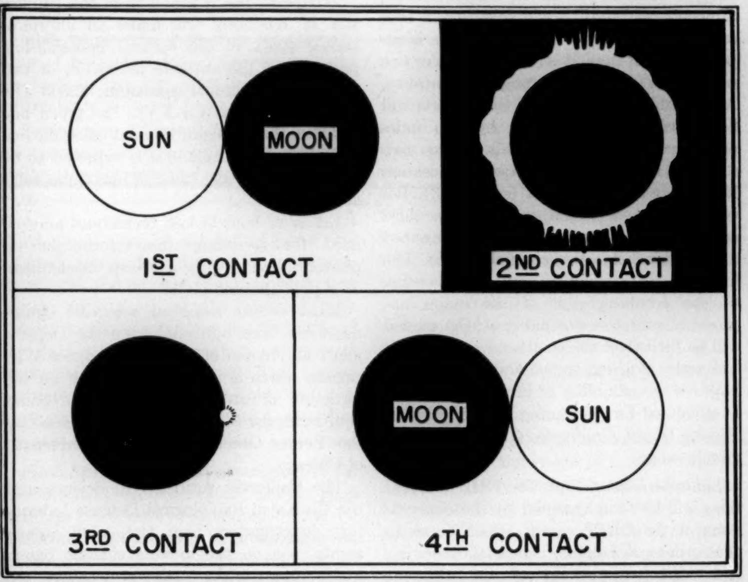

Fig. 3. *Progress of Total Solar Eclipse. The moon appears to overtake the sun in their passage across the sky:* (a) *The moon touches the edge of the sun (first contact);* (b) *The moon covers the sun and the corona becomes visible (second contact);* (c) *The sun reappears (third contact);* (d) *The moon passes the sun (fourth contact).*

Ionizing Sources: The Naval Research Laboratory plans to study the distribution of ionizing sources on the sun's disk and in the corona by direct measurement from rockets. NRL plans to fire a series of 6 to 8 rockets during the eclipse, two during the period of totality and the rest during the partial eclipse before and after totality. Each rocket will be equipped with detectors for soft X-rays (50 Å), harder X-rays (8–20 Å or 1–7 Å), and Lyman-alpha ultraviolet radiation (1216 Å). The rockets will be the Nike-Asp system, fired from shipboard approximately 10 miles from Pukapuka. Data recorded during the rocket flights will be telemetered to receivers aboard the *Thomaston.*

Each rocket will be in flight for approximately seven to eight minutes—about five minutes of which will be above the absorbing atmosphere. Totality will last about four minutes. As the most interesting data is expected at that time, it is planned to have two rockets in the air throughout totality. Aboard ship, data from the two rockets will be recorded simultaneously by two independent telemetering stations. These two rockets will be launched in quick succession just before second contact (see Fig. 3). Between first and second and between third and fourth contacts, rockets will be launched so as to bracket active coronal regions. The first in each pair will measure the solar flux as the occulting disk of the moon approaches an active coronal spot; the second will be fired after the spot is covered.

A series of firings to test and, if necessary, improve the reliability of the rocket system is scheduled for the spring of 1958 at San Nicolas Island, California, on the Pt. Mugu missile range.

Ionospheric Soundings: The NRL observations will be complemented by the observations of the CRPL group, which hopes to obtain data on heights, ionization densities, and critical frequencies of the different ionospheric layers by use of a modified vertical-incidence sounder. The sounder will operate from Motu Koe Island during the eclipse and for a suitable period before and after. Using pulses of radio energy, this equipment determines the heights and ionization densities of the ionospheric layers.

Because these layers are ionized by solar ultraviolet and X-radiation, a solar eclipse causes a marked decrease in ionospheric density. Correlation of the radiation data gathered by the rockets and the ionospheric data gathered by the sounder should give much information about the changes of ionospheric structure with changes in solar radiation. These two experiments can be carried on regardless of the amount of cloud cover.

Optical Experiments

Interferometry: A group from the University of Wisconsin will make an interferometric study of the coronal emission-line profiles and the absolute intensities of two lines of the coronal spectrum, $\lambda5303$ (Fe XIV) and $\lambda5694$ (Ca XV). The green line $\lambda5303$ is the strongest coronal emission line and the yellow line $\lambda5694$ is expected to be at its brightest at a time of maximum solar activity.

Either or both of two techniques may be used for recording the information: a photomultiplier with a sweep mechanism, or a photographic plate.

Most of the essential scientific equipment has been borrowed from the Department of Physics of the University of Wisconsin, where it is used in research on the structure of atomic spectral lines. Other equipment for the expedition was loaned by the Yerkes Observatory of the University of Chicago.

The California Academy of Science and the US Naval Radiological Defense Laboratory investigators plan two joint experiments, one on the moving shadow bands which appear in the earth's atmosphere just before second contact and just after third contact, and one on the polarization of the outer corona.

Shadow Bands: Measurements will be made of shadow-band phenomena by recording the output of photronic cells on a Helland Oscillograph Recorder during the period just prior to second contact and just after third contact. An array of 8 or 10 cells will be set up in some pattern as yet not wholly decided upon, but likely in the form of a cross, spaced at varying distances in an effort to obtain the direction, speed, and wavelength of the shadow bands. Each cell, measuring about 2 by 6 inches, will be mounted on a stake driven into the ground and connected to the recorder by a shielded cable.

Since it is generally believed that the shadow-band phenomena are produced by atmospheric discontinuities, it would be desirable to correlate the motions of the shadow bands with velocity and direction of winds aloft. It is hoped that NRL will be able to provide wind data by observations of balloons released sometime during the hour or two just prior to or just after eclipse time.

Polarization of Corona: A camera now under construction will employ a 20-inch focal length lens for obtaining photographs of the outer corona (white corona) in light polarized with respect to radial directions. A shutter consisting of a rotating sector will be used, and a sheet of polaroid will be rotated with the shutter. By an independent rotary adjustment of the polaroid with respect to the shutter, use can be made of the light polarized at various angles with respect to a radius. By use of filters, further restriction of the light can be obtained; this may provide added information regarding the polarization of the corona.

Flash Spectrum: A joint experiment of the Sacramento Peak Observatory and the High Altitude Observatory, sponsored by the US Air Force, will attempt to photograph the "flash spectrum" of the chromosphere. At the instant of totality the dark lines of the Fraunhofer spectrum appear to change suddenly to bright lines of chromospheric emission. The phenomenon lasts only a short time, perhaps 25 seconds at second contact and 25 seconds at third contact for the strongest lines, and the weakest lines may be observable for only 3 to 4 seconds in all. But observation of the flash spectrum yields information on structure and composition of the chromosphere which can be obtained in no other way.

In order to obtain the desired information on the corona, height resolution of the order of 100 km is necessary. This cannot be accomplished with a coronagraph, because errors of seeing in a man-produced "eclipse" blur height discrimination of distances far greater than 100 km. When the eclipse is produced outside the atmosphere, however, such height discrimination becomes possible—provided photographs can be taken fast enough. To do this, a spectrogram must be exposed every 0.3 second.

The equipment consists basically of a triple spectrograph to cover three spectral ranges: (1) 3300 Å to 6600 Å for the ultraviolet unit; (2) 3600 Å to 4900 Å in the visible; and (3) 5000 Å to 9300 Å in the infrared. Dispersions will be 5½ Å/mm in the ultraviolet and infrared and 2 Å/mm in the visible. The spectrographs will be fed by a single coelostat (a rotating mirror which follows the sun's movement). Each spectrograph will have a double camera unit, so that the speed requirement for a single camera will be one frame each 0.6 sec. Exposure is to be 0.2 sec, with film transport and shutter action to be accomplished in 0.4 sec. The size of each frame is 26″ by 7″.

Each frame will contain three separate spectra differing from each other in terms of intensity of the incident light in the ratio of 1 to 20 to 400. Also to be included on each frame will be the image of a step wedge illuminated by a lamp, to furnish a standard for comparison of the intensity of the spectra. Finally, there will be a serial number on each frame. The serial number will be used to identify the frame, so that it can be matched up with additional data (length of exposure, time, and so forth) to be imprinted on a multi-channel recorder. Absolute calibration will be provided by exposing spectra of the sun itself through the same optical system, both before and after the eclipse.

Expeditions by Other Countries

In addition to the US-IGY effort, at least two expeditions from other countries will conduct careful observations of the eclipse. The Japanese plan an extensive series of observations from a base on Suwarrow (Suvarov) Island, several hundred miles from the Danger Islands. The USSR has indicated that it will send an expedition but has not designated a site. New Zealand will establish a base at Atofu.

The Visual Auroral Program

Much of the following material has been adapted from a manual prepared by C. W. Gartlein and D. S. Kimball, Cornell University, for use in the IGY visual auroral program.

Auroras are the visible manifestation, in the earth's atmosphere, of a group of phenomena resulting from disturbances in the sun's interior and surface layers. They mark the paths within the atmosphere of the streams of solar particles ejected by eruptions on the sun. Hence, studies of the forms and global distribution of auroral displays do much to define these paths, as well as to determine the energies of the particles, the way they are trapped by the

Fig. 4. *Sample Auroral Report on Standard Graphic Card. The report, for 9:15 pm EST, shows a medium-intensity homogeneous arc (HA) extending from the western horizon to a bank of clouds 30° above the eastern horizon. As no color is indicated, the arc is either colorless or yellow-green. The HA reaches an angular height of 80° from the northern horizon—almost to the observer's zenith. To the north and at a height of 50° is a bright, eastward-drifting rayed arc (RA). Its lower margin is red. Rays (R) of medium intensity appear toward the northwest. They are vertical and extend from 8° to 20° above the horizon. No aurora appeared in the south. More elaborate sketches, or simple letter symbols, may also be used on these cards.*

earth's magnetic field, and possibly their acceleration within the atmosphere.

While auroras occur most frequently in high latitude belts circling the geomagnetic poles, auroras visible in middle and low latitudes, and especially in the tropics, are of special scientific interest. During the IGY, auroral displays in these regions in the northern hemisphere are being studied intensively by a large number of visual observers throughout the US and Canada.

Thousands of visual observations of auroras have been made in the past but systematic analysis in terms of form, time, location, height, extent, intensity, movement, etc. has been lacking. The IGY Visual Observation Program is designed to correct these deficiencies.

North American IGY Visual Observation Program

In the integrated, cooperative North American IGY program for visual auroral observation, personnel at meteorological stations of Canada and the United States are supplying much of the data. As other duties permit these participants to observe for short intervals only, many volunteer observers have been asked to assist. The volunteers are able to make more continuous and detailed observations than time allows the meteorological observers. Airline and ship crews are also assisting in the program.

In past visual observation programs, many observers have supplemented their written reports with sketches to show details of the arrangement of auroral shapes, structures, and movements. In one program the entire report was made in sketch or graphic form. This method was so satisfactory that it is used as the basis of the present volunteer program.

Reports are made graphically on a simple card which carries a diagram consisting of four quadrants representing the dome of the sky as seen facing south, west, north, and east (see Fig. 4). Completed reports are mailed to the IGY Auroral Data Center at Cornell University, Ithaca, New York.

Auroral Forms and Sequence

Auroras occur in a number of characteristic forms (Fig. 5), for which simple graphic representations have been standardized to facilitate reporting.

The various auroral forms usually occur in a specific sequence during a particular display, although the entire sequence may

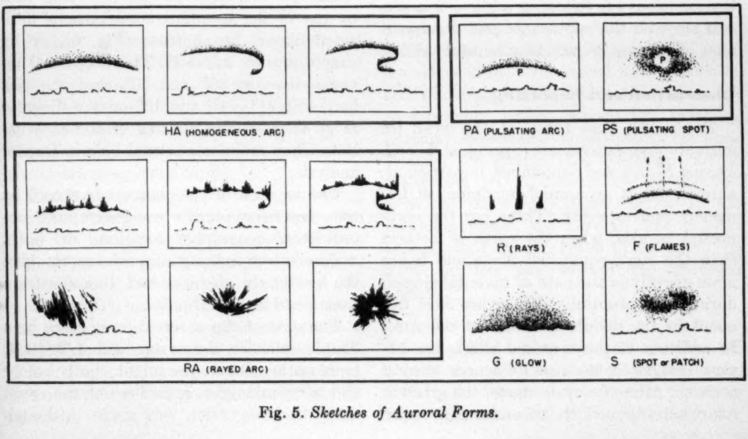

Fig. 5. *Sketches of Auroral Forms.*

not necessarily appear. Near the beginning of a display, predominantly homogeneous forms appear, glows (G) and homogeneous arcs (HA). There is little motion. A glow seen early in a display may actually be the upper part of a distant aurora whose lower border lies just below the horizon. The aurora may subsequently rise, revealing itself as an arc or a band. This may be repeated more than once.

Rayed forms showing considerable motion are characteristic of the second phase of the display. This phase, consisting of rayed arcs (RA), rays (R), and sometimes flames (F), is the main part of the display. It is accompanied by increased luminosity and the appearance of distinctive colors.

The declining phase of the auroral display is characterized by indistinct patches of luminosity, sometimes spotty (S) and with scattered, diffused rays; glows, which may persist for several hours; pulsating forms (P); and occasionally rays or flames.

Changes in auroral forms during a display are believed to be associated with changes in the earth's magnetic field, earth currents, and ionosphere. Of particular interest are changes of one form into another, such as a homogeneous arc into a rayed arc; the appearance of a new form, such as a homogeneous arc following a glow, or a second arc; and the appearance and disappearance of flaming or pulsating auroral forms.

Observation and Reporting

Time: The best times of the year for auroral observations are Spring and Fall. During March and September, in particular, auroras are at an annual maximum of frequency and intensity. These are the equinoctial periods, when the earth is farthest from the sun's equatorial plane and hence more directly in the path of material ejected during solar eruptions. (These are most frequent in the middle latitudes of the sun.) In addition to this seasonal effect, the 11-year sunspot cycle also influences auroral activity. After the cycle starts, the greatest solar activity, which means many solar eruptions, occurs in middle solar latitudes. Later in the cycle, although eruptive activity takes place nearer the sun's equator, such activity diminishes considerably. As a result of the combined effects of these seasonal and cyclical factors, auroral activity reaches a peak about a year after the sunspot maximum.

Although auroras are usually more frequent during the periods March–April and August–September, observation is not restricted to these months. Northern observers make observations each possible night throughout the year. A report of no aurora on a clear night may be as important statistically as the record of a brilliant display, particularly during times of Alerts and Special World Intervals (SWI) declared by the IGY World Warning Agency (WWA). (*Bulletin No. 5*, November 1957, contains an outline of the IGY Special World Days Program for coordinated intensification of upper atmosphere observations during times of heightened solar activity.) In latitudes below about 40°N, where auroras are rare, observations are made primarily on nights when geomagnetic disturbances are expected, i.e., during Alerts and SWI.

Reporting auroral forms: The auroral forms are indicated on the reporting card by use of the standard abbreviations indicated above, by sketches (Fig. 5), or by simple graphic symbols. The horizontal division lines at 30° and 60°, and the tick marks at 21°, 14°, and 10° on the diagram (Fig. 4) guide the plotting of the observation. They are also essential aids in further analysis.

The location of the observer is shown on the reporting card by geographic coordinates, geographic location, or both. Airline crews making auroral reports give the location by distance and direction from some nearby control point.

The date of the observation is given as a double calendar date, e.g., Jul 1/2 1957, representing the entire night, both before and after midnight, regardless of the exact time the observation was made. Although regular observations are made as nearly as possible every quarter hour, the exact time of an observation is recorded to the nearest minute on a 24-hour basis, e.g., 23^h42^mEST or 2342EST.

Visibility: Clouds, haze, fog, twilight, moonlight, and other factors affecting light conditions in the sky determine the visibility of a given aurora. They also affect it indirectly by changing the brightness of distant city glow. Such conditions are recorded in the diagram by circled abbreviations.

Location: When the lower border of an auroral form, generally about 100 km (62 mi) above the earth's surface, is seen 60° above the horizon, the form is located over a point on the surface about 30 mi from the observer. Thus, the upper ⅓ of the quadrants on the diagram contain reports of auroras occurring within a radius of approximately 30 mi of the observer's location. Similarly, the 30° lines define a circle with a radius of about 90 mi centered on the observer. The short tick marks represent lower elevations above the horizon and define circles of greater radii. In this way, a complicated mathematical transformation is effected in a simple, graphic manner with the required precision.

Heights of auroral forms: Measurement of the angular height of an auroral form is made by visual estimate or by use of devices for determining vertical angles, such as theodolites, air navigation octants, inclinometers, and alidades. Forms near the zenith are of special interest.

Observers possessing suitable measuring devices determine the angular elevation from the horizon to the lower edge of each form whenever possible. Angular elevations to the top of isolated ray forms are also measured. To aid the individual observer in the measurement of angular elevations, a simple inclinometer has been designed. Though light enough to be held in the hand, this instrument can give measurements accurate to within 1°.

A program using a more complicated and more precise instrument, the alidade, has been designed for groups of observers who can work consecutively during a major portion of the night. Participants in this program report the same data as the individual observers, but confine their observations largely to the meridian. Measurements are plotted on a card designed to fit into a slot on the instrument.

Intensity: The intensity of an auroral display is indicated by writing standard letter symbols next to the auroral form on the reporting card. A weak, or faint, aurora is approximately equivalent in brightness to the milky way; auroras with the brightness of a moonlit cirrus cloud are considered medium. Bright auroras have about the intensity of moonlit cumulus clouds, and very bright displays are much brighter than this.

Motions: Auroras commonly display characteristic motions. Drift motions—slow, steady, east-west motions that appear to vary systematically during the night—are observed as slow changes in position of an entire form. Drift is not immediately apparent as the forms normally move only a few degrees per minute. On the reporting card, the drift is shown by a horizontal arrow pointing in the direction of movement.

The expansion of the entire auroral zone is evidenced by a slow southward motion of the whole aurora, in which the forms rise progressively higher above the northern horizon, sometimes approaching or even crossing the zenith. This expansion can be recognized by comparing an observation with one made 15 minutes earlier. In the declining phase, the auroral zone is contracting and the motion is to the north, or lower in the sky toward the northern horizon.

Colors: Auroras are often of such low intensity that colors are not apparent. If this is the case, or when the color is the usual yellowish-green, the observer makes no report on color. Other colors, usually red, blue, or violet-grey are rare—occurring only about $\frac{1}{20}$th as frequently as the yellow-green—but significant. These are reported. Red may appear extensively in a display, especially in low latitudes. (An aurora that occurred on February 10/11, 1958, and was seen as far south as Cuba, was reported by many observers as red in color.) The red color may appear at the lower borders of arcs or bands, at the tops of rays, or as diffuse clouds.

Optical devices: A number of simple optical aids are used by visual observers. Color filters help to distinguish auroral forms and colors as well as screening out moonlight and scattered city light. Still, time-lapse, and color photography are used by many observers to provide permanent visible records of auroral events. Pairs of photographs taken of the same aurora from different ground locations permit accurate height determinations.

Status of the Program

By January 1958 about 430 active observers were taking part in the visual auroral program. Approximately 130 US Weather Bureau stations, most of them reporting hourly, and 30 airline pilots are participating. The IGY Auroral Data Center is receiving about 5000 reporting cards per month from the Weather Bureau and roughly 6000 per month from volunteer observers. To date, more than 36,000 auroral reports and more than 350,000 reports of no aurora have reached the Data Center. More than 1200 cards were received on the aurora of February 10/11, 1958. This extensive aurora was, therefore, the world's most widely observed display up to that time.

Based largely on data received from participants in the visual observation program, synoptic maps are being prepared on a 15-minute basis for every aurora reported in the United States (see Fig. 6). The maps show the overhead location of the aurora and its shapes, intensity, changes, colors, and movement. Data accumulated during Special World Days and Special World Intervals are making it possible to construct similar maps of the distribution of

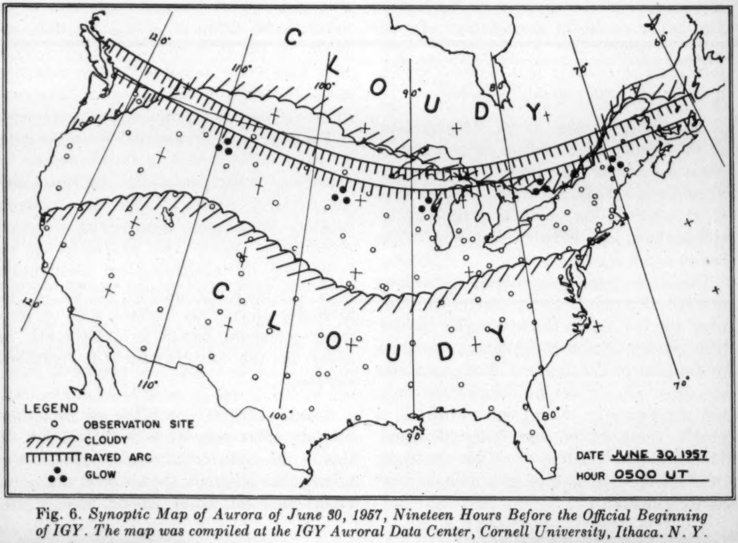

Fig. 6. *Synoptic Map of Aurora of June 30, 1957, Nineteen Hours Before the Official Beginning of IGY. The map was compiled at the IGY Auroral Data Center, Cornell University, Ithaca. N. Y.*

auroras over the entire globe for these periods of increased auroral activity. The maps prepared are microfilmed for international exchange.

Early Results: A number of interesting auroral features have already been reported in the Visual Observer Program. In large auroras, displacements of the coronas have been observed. Coronas, or radiant crowns, are formed when rays appear to converge (a perspective effect) as they approach the magnetic zenith—the position in the sky toward which the magnetic dip needle points.

Four months of Weather Bureau observations indicate that auroral motions are greatest at about midnight, and are predominantly from west to east.

The aurora is probably visible over the entire night side of the earth; continuous arcs have been observed for more than 2000 miles, and simultaneous auroral events have been observed from the English Channel to Ohio.

Arctic Sea-Ice Studies

This report is based on material supplied by Norbert Untersteiner, Department of Meteorology and Climatology, University of Washington.

As part of the IGY program for study of the earth's heat and water budget (described in *Bulletin No. 2, August 1957*) investigations of the physics of sea ice and the heat and moisture exchanges across the ice-atmosphere and ice-ocean interfaces are being conducted on IGY Drifting Station A in the Arctic Ocean ice pack (see Fig. 7).

The primary objective of these studies is to obtain data on the relative influence of the transfer of radiative heat and of latent heat on the mass budget of sea ice. (Radiative heat is heat released by emission or absorption of electromagnetic waves; latent heat is heat released by the change of state of water, i.e., melting, freezing, evaporation, condensation, etc.) Transfer of heat between the ocean and the atmosphere by conduction through the ice is also being studied. The investigations are scheduled to be carried out over a period of at least 12 months. This report covers some of the preliminary results of work done during the period June–September 1957.

The work is being carried out by the University of Washington Department of Meteorology and Climatology. IGY Drifting Station A, on a seven-foot-thick ice floe with an area of about four square miles, was established and is supported and maintained with the help of the US Air Force. It was first occupied on April 5, 1957; its position on April 24, 1958, was 84°N, 152°W, about 375 mi from the North Pole

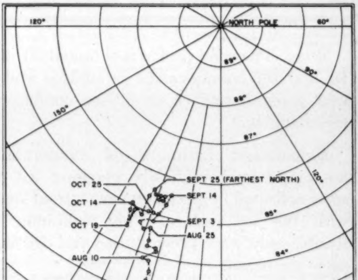

Fig. 7. *Movement of US-IGY Drifting Station A in Arctic Ocean, May 27–October 25, 1957.*

and 925 mi north of Barrow, Alaska. All equipment was installed on the drifting station by mid-June, well before the onset of melting.

Drifting stations are advantageous for studying the earth's thermal budget and other meteorological factors since they are distant from land masses and are surrounded by a uniform surface, conditions that make the data accumulated representative of a large area.

Techniques of Observation

Radiation: A radiometer is used to measure separately the total amounts of both incoming and reflected radiation; solarimeters measure the incoming and reflected short-wave radiation.

Temperature: Air temperatures are measured at 25, 50, and 100 cm above the ice by use of copper-constantan thermocouples. Thermocouples installed at three sites also measure temperatures at four levels in the ice. Ocean temperatures at a depth of three meters below the ice are obtained by use of additional thermocouples. A 16-point recorder is employed when continuous records are required.

Wind: The wind profile is obtained 20, 40, 80, and 160 cm above the ice surface whenever general weather or surface conditions are changing.

Evaporation: Estimates of evaporation are made by periodically weighing ice or snow collected in plexiglass pans buried level with the ice surface. This technique is feasible only when precipitation and drifting snow are absent.

Mass Budget Measurements: Direct evaluation of the change in total mass of the ice pack has been difficult. Measurement of ablation (loss of snow or ice, primarily by melting) at 16 localities appears to have established satisfactorily the loss of solid ice. But the initial amounts of snowfall and of melt beneath the cover of snow and slush could only be estimated. Too many observation sites would have been needed for an adequate measure owing to the collection of water in many depressions on the irregular surface of the floe, and to the extent of natural and artificial drainage.

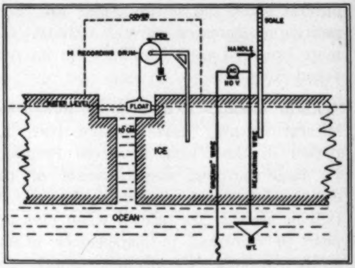

Fig. 8. *Water-Level Recorder (left) and Instrument for Measuring Accretion and Ablation at the Bottom of the Ice (right). The recorder utilizes a float placed in sea water which partially fills a pit; at the bottom of the pit a hole is drilled through the ice to the sea. A pen records water-level fluctuations on a drum.*

Mass changes at the ice bottom are measured by the other device. It consists of a measuring wire extended vertically through the ice; a cross bar is attached at the bottom. The wire, normally frozen into the ice, can be released by sending a current through a circuit completed by a second wire reaching the ocean. The measuring wire can then be pulled up until the cross bar touches the ice bottom. Readings are made on a scale fixed in the ice.

In anticipation of these difficulties, a water-level recorder was set up to determine relative height changes between the water surface and a fixed level in the ice (Fig. 8). This indicated how far the ice floe rose after natural and artificial drainage and how much lower in the sea it floated under a mantle of new snow. These records, however, do not distinguish mass changes at the surface from those at the bottom of the ice. Moreover, the instrument is only 1/9 as sensitive to ablation and accretion at the ice bottom as it is to these factors at the ice surface. In order to make the bottom measurements more accurately, another instrument was devised (also shown in Fig. 8). In addition, total thickness can be determined with greater ease and accuracy using this device than by drilling to the bottom of the floe.

Additional Measurements: Measurements are also made of the thickness and density of the ice, chlorine content (or salinity) of the sea water, and surface temperature (with thermocouples).

Accumulation and Ablation at the Surface of the Ice

An estimated 40 cm of snow, with a density of 0.3–0.4 gm/cm^3, accumulated during the winter and spring before melting began. Melting, which started in mid-June, was rapid owing to the low albedo (percentage of visible light reflected by a natural surface) of water and water-saturated snow. The snow cover had almost completely disappeared by July 8. Stakes were then emplaced for measurement of ice ablation, which averaged about one cm/day during the main ablation period, July 9–24.

Following the ablation period, a blanket of new snow began to develop, occasionally interrupted by brief melting periods. After August 8, however, accumulation increased steadily. The new snow cover reached a depth of approximately 20 cm by the end of September. Figure 9 summarizes the results of these accumulation-ablation observations during the summer of 1957 and Figure 10 portrays them diagrammatically.

During early July, the melt water ponded on the surface reached its greatest extent, covering approximately 30% of the total surface area. On July 3, when the water-level recorder was installed, the temperature of the central portion of the ice (at depths of 150–200 cm) was −3.5°C. Ice at these depths was essentially impermeable to melt water, and run-off over the edges of the floe was negligible. Therefore, virtually all melt water that had collected by early July still remained on the surface of the floe. By mid-August, holes had been melted through the ice, allowing the water to drain off and the floe to rise higher in the sea.

Water Level Records: As shown by water-

Fig. 9. *Graph of Mass Changes and Vertical Movement of the Ice Floe During the Summer of 1957.*

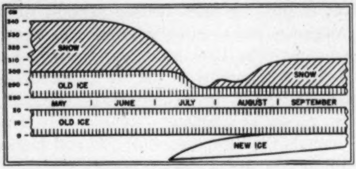

Fig. 10. *Schematic Diagram of Mass Changes, May–September 1957.*

level records, the ice floe rose a maximum of 29.6 cm from June through August 15, 1957. This is equivalent to a loss of 32.8 cm of ice. As determined by ablation measurements, on the other hand, the total ice loss, including melting of the spring accumulation of snow, was 26.5 cm. The difference of 6.3 cm may be accounted for by assuming a greater ablation in melt-water ponds, which covered 15–30% of the surface area for a three-week period. (The dashed line in Figure 9 indicates that ablation beneath 15 cm of water is approximately twice as great as that of bare ice.)

It is not possible to use the water-level records for ablation determinations over short periods. However, they appear to give reliable values for total ablation. A further practical characteristic of these records is the fact that they show runoff, or the amount of ice actually removed from the surface, rather than melting.

Stake Readings: For the period July 25–September 6, stake readings indicate a total accumulation of 3.4 cm of ice. The ice accumulation shown by the water-level recorder for the same period was 2.4 cm. Again the stake readings are considered less reliable as they represent level-ice conditions and do not account for the effects of the numerous hummocks or mounds. No appreciable accumulation was shown during this period by four stakes set on hummocks, which were about one meter high and 15 meters across.

Accretion and Ablation at the Bottom of the Ice:

On July 21, drilling revealed a newly-formed ice layer 1–3 cm thick beneath the pack ice. A layer of fresh water or slushy ice, with a temperature of 0°C and of varying thickness, separated it from the previous ice bottom. Further drilling showed that the distribution of this fresh-water layer was related to the topography of the underside of the pack ice. Pools formed under places where the ice was thin (about 250 cm) and were absent beneath hummocks and thick ice (greater than 300 cm).

Early in its development, a sample of this new ice was obtained with a coring auger. It was practically free of salt. At one locality, the layer had grown to a thickness of 20 cm by July 25. Here, the new ice was separated from the original ice bottom by 12 cm of fresh water. A constant temperature of −1.6°C was recorded in the ocean water beneath the new ice layer.

Manner of Formation of New Ice Layer: The layer of new ice appears to form as follows: Fresh surface melt water seeps through drain holes and pores in the pack ice, eventually accumulating at the ice bottom. There it floats on top of the cold, heavier ocean water. Fine, needle- and plate-like ice crystals develop between the fresh and salty water. These unattached crystals rise, gradually forming a loose, delicate fabric in the layer of fresh water, too tenuous to be felt when drilling. When these newly formed crystals can no longer rise, a solid layer begins to develop along the boundary between fresh and salt water, at the bottom of the network of fine crystals.

It was observed during August that this sub-layer of new ice, once formed, appeared to move upward while showing little increase in thickness. It seems unlikely that this rise was caused by buoyancy as it is assumed that the fine crystal network filling the fresh-water layer would be resistant to the buoyant force of ice forming along its lower margin. Probably, the rise of the top of the sub-layer actually results from freezing of the fresh-water layer, and the rise of its bottom surface represents melting of the fresh ice by the action of salty ocean water. The latter assumption is supported by the observation that the ice continued to thin even after the fresh-water layer above it had completely frozen. This bottom ablation may end when surface cooling penetrates to the bottom of the ice pack.

The formation of this sub-layer of 20 cm of fresh ice by July 25 indicates unexpectedly rapid freezing. The growth of the sub-layer with time can be expressed by the equation—

$$s = -1 + (4 + 17t)^{1/2},$$

in which s = thickness in cm, and t = time in days. Under the ideal conditions implied in the formula, the thickness of the ice layer would increase from 1 cm to about 23 cm in 20 days. This agrees well with the observed increase. However, the formula neglects the possible ablation of the bottom of the sub-layer owing to the action of salt water; hence, it tends to give a maximum thickness. Moreover, if accumulations of fresh water under the pack ice were initiated during an interval of rapid ice drift (from June 17 to July 17 the average drift of the floe was 8 km/day) and turbulent mixing, a fresh-ice layer might not form at all.

Mass Budget: The formation of this sub-layer of fresh ice may be of basic significance in the mass budget of the ice pack.

Studies up to the present lead to the assumption that throughout the Arctic Basin sufficient heat is supplied during part of the summer to melt the recent snow cover as well as a certain amount of solid, or "old," ice. The thickness of the pack ceases to change when the annual accretion at the bottom of the ice is equal to summer ablation. Much of this bottom accretion may consist of the fresh-water ice. This possibility will be investigated further when studies of the salinity of pack ice are carried out.

Owing to continuing accretion at the bottom of ice of stationary thickness, it is assumed that there is an upward movement of mass within the ice pack. It should be expected, therefore, that on a very old, unbroken floe, the oldest ice lies immediately beneath the surface layer of new spring ice.

Thermal Budget

Data evaluation thus far permits only a few preliminary statements about the summer thermal budget. It is apparent that long-wave radiation is of great importance in surface melting. Throughout the observation period, melting occurred primarily when the sky was overcast and atmospheric radiation was strong. Freezing at the surface often accompanied short breaks in the overcast. Balloon soundings revealed frequent inversions in atmospheric temperatures, with comparatively high ceiling temperatures.

During melting, the pack-ice surface disintegrates into a loose layer of coarse, granular ice, which has a high albedo—higher than that of clean glacier ice. This may result from a difference in crystal structure and the penetration of radiation into the pack ice.

Temperature gradients in the layer of air just above the ice surface are usually very small or virtually lacking, according to measurements made 25, 50, and 100 cm above the ice. The humidity regime in this layer appears to be similar to the temperature regime. Direct measurements, made by weighing snow-filled pans, indicate that maximum evaporation occurred on June 29. A heat loss of 30 cal/cm^2 over a period of 12 hours was measured on this date. The maximum condensation, involving a heat gain of 16 cal/cm^2 in 12 hours, took place on September 14. Average heat gain is normally only several cal/day.

On the basis of observations made during the June–September 1957 period, it is expected that further data will show radiative heat to be the most important element in the summer thermal budget and in melting. The transfer of both sensible heat (heat released by turbulence or molecular conduction) and latent heat appear to be less significant.

Optical Tracking of Earth Satellites

This report was compiled from materials furnished by the Smithsonian Institution Astrophysical Observatory, Cambridge, Massachusetts, which directs the US-IGY optical tracking program. Reports on other satellite tracking programs may be found in *Bulletins 6* and *10* (volunteer visual and radio tracking), *2* (prime radio system), and *9* (volunteer photographic tracking).

Of the several satellite tracking programs designed for the IGY—radio, visual, and optical—it is the optical which is intended to obtain orbital and positional data of maximum precision. Once a satellite is located, or "acquired," by other means, and its orbit computed, precision optical tracking is accomplished by large tracking cameras. These tracking cameras cannot be used for acquisition because of their relatively restricted field. (The path of the satellite must first be known to within 3° of arc in order to aim the cameras.)

Baker-Nunn Tracking Camera

The precision camera designed for the US-IGY satellite tracking program is the Baker-Nunn camera, a modification of the Schmidt meteor camera.

Under optimum conditions, the Baker-Nunn tracking cameras will measure a satellite's position to an accuracy of two seconds of arc and $1/1000$ second in time. The camera is named for James G. Baker, who designed the optical system, and Joseph Nunn who designed the mounting, tube, drives, and other mechanical parts.

Fig. 11. *Two cross sections of the Baker-Nunn satellite-tracking camera, showing the film-transport and shutter mechanism. The two halves are at right angles to each other, and all dimensions are in inches. The double-walled camera case is in four sections (right to left), one holding the mirror, the next the support trunnions, the next the focal surface and film-transport system, and the last the three-element Schmidt correcting plate.*

Optical System: This camera utilizes a Schmidt optical system with a new type of correcting system. It has a focal length of 20 inches, an aperture of 20 inches (thus giving a focal ratio of f 1.0), and a field of 5° x 30°. The camera uses 55-mm Cinemascope film. Each photograph is about one foot long. The complete optical system is shown in Figure 11.

Camera Mounting: Use of a three-axis mounting permits the camera to track in any direction across the sky. For tracking, two axes are clamped in fixed positions and the camera body is rotated about the third axis by an electric drive.

TABLE 1

Angular Velocity (min of arc/sec)	*Limiting Magnitude*	
	Stationary	*Tracking*
87.8	5.8	10.8
42.1	6.6	11.6
19.4	7.4	12.4
8.9	8.3	13.3
0.25*	12.2	17.2

* This is the sidereal rate at the celestial equator. In this table, it is assumed that 80% of the light falls within a 30-micron circle. The satellite-tracking cameras in the US-IGY program exceed this efficiency.

Position Measurements: Traditional astronomical methods of measuring image positions relative to star images on the film are necessary in order to achieve the precision of two seconds of arc. When the satellite is tracked at maximum orbital velocity, the stars will trail and only those brighter than approximately 5.8 magnitude will be recorded. Usually, only two or three stars of this brightness can be expected to fall in the 5° x 30° field. If measurements must be made from the star image to the satellite image across several inches of film, stretching of the film and distortion of the emulsion will introduce greater errors than can be tolerated.

In order to avoid long measurements, the camera tracks alternately at the satellite rate and at the rate of sidereal (star) motion parallel to the satellite orbit. In this way exposures of both the satellite and the background of faint stars can be made on a single film. The satellite position is then measured relative to nearby star images. Satellite motion between the two exposures is compensated for by measuring the distance between the "star-exposure" images of the bright stars and the "satellite-exposure" images of these same stars. This distance will never exceed one inch, and the amount of film stretching over this distance will not introduce excessive error in the measurements.

A time reference is provided by using a rotating barrel-type shutter which causes sharp breaks in the trails of both the satellite and the bright stars. This shutter is shown in the upper part of Figure 11 as a cylinder enclosing the film back-up plate. Outside the barrel shutter is a "clamshell" shutter which opens and shuts to begin and end each exposure.

Tracking Cycle: For each film exposed, the camera automatically runs through a basic cycle that can be set at 2, 4, 8, 16, or 32 seconds. During this cycle, the tracking rate varies from sidereal to satellite and back again.

To begin the cycle, the clamshell shutter snaps open for an interval of 0.1 cycle, during which the exposure is chopped into four segments by the continuously rotating barrel shutter. At the instant of some one chop, a stroboscopic flash illuminates the time-display unit attached to the camera and the time is recorded photographically. After the clamshell closes, the tracking rate decelerates to the sidereal rate and the clamshell opens again for 0.1 cycle. This star exposure is likewise chopped into four segments, but the time is not recorded. After the shutter closes again, the film is automatically changed and the cycle repeats.

Effective Exposure: The setting of the mean tracking rate is continuously variable and in practice can be adjusted so that the camera tracks the satellite with an error of one percent or less. Tracking increases the effective exposure time by a factor of 100 over that possible if the camera remains stationary. This increase in effective expo-

sure means that objects five magnitudes greater than otherwise possible can be photographed. Table 1 shows the limiting magnitudes for different tracking rates.

Time Measurement: The greatest possible angular velocity for a satellite in orbit is 5300 seconds of arc per second of time. Thus, a measuring accuracy of two seconds of arc in the direction of motion in this extreme case requires a determination of time to $1/2500$ second. Such accuracy cannot be maintained under field conditions but the time unit used on the camera does allow time measurements to $1/1000$ second.

The primary component of the time unit is a crystal clock. Added to this are a radio receiver for WWV time signals, a system of time presentation readable to $1/10.000$ second, and a "slave" clock that will duplicate the time presentation within the body of the telescope, where it can be photographed during each operating cycle of the camera.

The time presentation includes a rotating dial that indicates time to $1/100$ second, and an amplitude-modulated circular-sweep oscilloscope which can be read to $1/10.000$ second. This displays the output of the clock and compares it with the signal received from WWV. If daily comparisons with WWV are made, the error of this time system is held to $1/1000$ second.

Tracking Stations: The first Baker-Nunn Camera was installed at Organ, New Mexico, on November 15, 1957. Table 2 shows the location of all 12 precision photographic tracking stations of the US-IGY program.

Of the nine stations established outside United States territory, six are operated in cooperation with the IGY committee and other scientific organizations of the nations concerned. Australia, Japan, and India have assumed complete operating responsibility for their stations. Other countries have provided varying degrees of support in the form of personnel, sites, facilities, operating expenses, and communications. In addition to this extensive international cooperation, the optical tracking program has received valuable logistic and operational support from the US Air Force, Army, and Navy.

The locations were selected to give maximum coverage on satellites with orbits inclined at 35°–40° to the equator.

Through a special communications network, the Smithsonian Astrophysical Observatory provides each station with information on camera settings for each visible pass of each satellite. Each station develops the films as soon as possible, makes preliminary reductions of position data, and sends the information to the Astrophysical Observatory through the same communications net. The negatives are forwarded later for detailed analysis.

Gravity Measurements in the Queen Elizabeth Islands of Arctic Canada

A. M. BANCROFT

Abstract—Principal facts are presented for five gravity stations in the Canadian Arctic north of latitude 74° N. The accuracy of the measurements is discussed, and station descriptions are included so that the gravity sites may be used as bases for further work in the Queen Elizabeth Islands.

Introduction—The extension of our knowledge of the Earth's gravitational field to more remote regions is essential if the world-wide geodetic applications of gravity are to be utilized. The establishment of five permanent weather reporting stations in the Queen Elizabeth Islands since 1946 [*Rae*, 1954] has made access to this region possible (Fig. 1). The annual resupply of the four northern stations from Resolute by the Air Transport Command of the RCAF has enabled the Dominion Observatory to employ gravimeters to make measurements at all five stations.

The area is interesting historically in that the first measurement of gravity in Canada was made at Winter Harbour, Melville Island in 1820, during the Parry Expedition of 1819–20 [*Sabine*, 1821]. Pendulum measurements were also made at Fort Conger in northern Ellesmere Island during the ill-fated Greely expedition [*Greely*, 1888].

Previous work—Apart from Sabine's work, the first measurement of gravity in the Queen Elizabeth Islands was made in 1948, when graduate students of the University of Toronto established a pendulum gravity station at Resolute [*Beer*, 1950]. This result, coupled with previously established pendulum stations at Churchill and Ottawa [*Innes*, 1948] made it possible to calibrate a geodetic-type Worden gravimeter (No. 44) by flying between Dorval Airport (Montreal), Churchill, and Resolute Bay. This was done in 1951 by P. M. Millman, in 1952 by J. A. Robinson, and in 1953 by M. J. S. Innes and J. A. Robinson. The adjustment of the results of these calibrations gave a value at Churchill Airport of 981.7668 gal (Table 1). This figure was in satisfactory agreement with a value of 981.7670 found by an overall adjustment of the pendulum station values of gravity in northern Ontario, Manitoba, and Saskatchewan [*Innes* and *Thompson*, 1953]. The mean value of gravity which is adopted in this report is therefore $g = 981.7669$ gal at the Churchill Airport site.

The mean gravimeter value obtained with the Worden instrument at Resolute Airport (Table 1) will be referred to later in this report.

Gravimeter observations at the other weather stations have been made by J. A. Robinson in 1952 and by United States observers [*Woollard, Black*, and *Bonini*, 1954]. As there is some uncertainty about station locations the results have not been compared with the 1957 observations presented here.

The observations—The gravimeter used was a North American instrument (No. 137) with a range of 1200 mgal. This instrument has considerably greater accuracy than Worden meter 44 when measuring gravity differences greater than about 100 mgal. (The errors in the Worden instrument are dominated by temperature effects and by uncertainties in the calibration of the large dial). With the present instrument a special light-weight battery was used, composed of four silver-zinc cells strapped around the carrying frame (Fig. 2). The whole was arranged to be carried on the observer's chest rather than his back. The battery was successfully used for periods of up to 30 hr before recharging.

An additional refinement has been incorporated into this gravimeter by R. L. G. Gilbert of the Dominion Observatory in an unpublished study undertaken in 1957. This consists of a sapphire ball, 1/16 inch in diameter, which can be lowered onto the beam of the instrument; the change in reading (about 350 divisions) is determined. This enables the calibration constant of the instrument

to be checked for changes with time, latitude, or the position of the reading dial.

The instrument was taken twice from Churchill to Resolute, readings being taken in every case immediately before departure and upon arrival; this operation was completed in 31 hr. Two round trips were made from Resolute to each of the other four weather stations, the flights to Mould Bay and Isachsen being made in quick succession, so that a satisfactory correction for instrumental drift could be made. The two flights to each of the other two stations were made on separate days so that the results do not have quite the same strength. However, all eight sorties from Resolute were completed in nine days so that in view of the nature of the operation it is felt that the time between repeat readings was kept satisfactorily low.

FIG. 2 - Reading the gravimeter at Resolute; the carrying frame with the silver-zinc cells attached is directly in front of the instrument

Care was taken in the descriptions of the sites of the gravimeter bases (Figs. 3 and 4). The gravity stations at Churchill and Resolute are the same as those used by previous Dominion Observatory parties. At the other four weather stations the

gravimeter was read on the floor adjacent to the barometer in the operations building. This was done because in each case the elevation of the barometer was known, and the chances are improved for recovery of the gravity stations by future observers.

The results—The values of gravity presented here are based on the adopted value of *g* at the Churchill Airport station of 981.7669 gal.

The gravimeter readings were first corrected for diurnal variations caused by the changing attractions of the Sun and Moon, using the tables of *Goguel* [1956]. Next, the readings were corrected for instrument drift and values of the difference in reading (ΔR) were computed. Lastly, the mean ΔR for each connection was calculated. These results are summarized in Table 2. They are presented here to allow their reliability to be independently assessed, and because when improved pendulum observations are available, the data will be needed in a final adjustment.

The conversion of the ΔR values to gravity differences is based upon a calibration of the instrument along the Ottawa – Washington base line [*Saxov*, 1956]. In June 1957, the calibration constant obtained was $K_{137} = 0.23914$ mgal/div.

Tests made by weighing the sapphire ball in May and in June indicated that the May 1957 value was the better value to adopt for the period of the survey. This was $K_{137} = 0.23927$ mgal/div.

Additional tests carried out with the sapphire ball at Churchill and Resolute gave secondary scale constants: $K_{137} = 0.2392$ mgal/div for Churchill – Resolute; and $K_{137} = 0.2390$ mgal/div north of Resolute.

The decision not to accept the indicated change of scale constant with latitude was largely based upon the uncertainty of the ball tests at Resolute. The graph of the effect of the ball plotted against dial position does not have the same form as at other locations, which makes the reliability of the Resolute measurements suspect. Gravity values have therefore been computed using the calibration constant $K_{137} = 0.23927$ mgal/div throughout. The observed gravity differences are added to the adopted value at Churchill to obtain the observed value of gravity at each of the other stations.

The final results are presented in Table 3. The computed values of gravity are calculated according to the International Gravity Formula, first at sea level and then at the elevation of the station for both the free-air and Bouguer reductions. In the free-air reduction no account is taken of the material between station elevation and sea level, while allowance is made in the Bouguer reduction assuming a rock density of 2.67 gm/cc. The differences between the observed and computed values give the free-air and Bouguer anomalies listed in the last two columns.

It is interesting to note that the value of gravity for Resolute presented in Table 3 is only 0.4 mgal less than the previously adopted value based upon a combined analysis of pendulum measurements and the readings of the Worden instrument 44 (Table 1). In view of the uncertainty of our knowledge of the large dial/small dial ratio of the Worden instrument no attempt has been made to combine the results.

An estimate of errors can be made only in the broadest terms. With the exception of the Resolute – Eureka connection, the scatter in the individual determinations of ΔR is less than one division, so that the error due to this source is not more than 0.2 mgal. On the other hand, systematic errors due to the uncertainty of calibration may be considerable. An error of one part in 1000 in the scale constant determination, which is not inconceivable, would result in an error of more than 1 mgal in the Churchill – Resolute connection alone. Hence, while the values of gravity are probably consistent among themselves to better than 0.2 mgal, they may be too high or low relative to Ottawa by about one mgal. However, until such time as improved pendulum determinations can be made, the values published here should prove quite adequate for both geodetic purposes and as base stations for further observations in the Queen Elizabeth Islands.

Planetary Waves and Jet Streams in the Atmosphere*

S.-K. KAO

Abstract—A systematic analysis of planetary waves in a zonal current with jet stream, linear velocity-shear, and uniform angular velocity shows that (1) the phase velocity of the planetary waves in a zonal current with jet stream increases or decreases depends respectively on the narrowing or broadening of the jet stream, (2) the increase or decrease of the dimension of the planetary waves follows respectively the broadening or narrowing of the width of the jet stream, (3) the major effect of a linear velocity-shear in a zonal current is to damp out waves in the current, (4) the streamline pattern in a zonal current on a spherical Earth with uniform angular velocity exhibits major characteristic features in the atmosphere such as subtropical highs, jet stream, westerly waves, high latitude lows and polar easterlies, and (5) the effect of viscosity is to damp out all waves in the current.

Introduction—The discovery of planetary waves in the atmosphere may be considered as one of the important discoveries in the modern history of meteorology. The reason for its importance lies in the fact that planetary waves are closely coupled with weather systems and are semi-permanent, a characteristic which makes it easy to be predicted. The development of planetary wave stems from the principle of the conservation of absolute vorticity. Applying this principle to the study of atmospheric motion *Rossby* and collaborators [1939] obtained a wave solution on an Earth whose variation of Coriolis parameter with latitude is constant. Since then planetary-wave solutions of the vorticity equation for an inviscid fluid have been investigated by *Haurwitz* [1940 ab], *Ertel* [1943], *Craig* [1945], *Rombakis* [1948], *Höiland* [1951], and *Long* [1952], and for a viscous fluid by *Kao* [1954, 1955]. In recent years, synoptic analysis shows that the field of motion in the middle and upper troposphere is characterized by the presence of jet streams, planetary waves, and cyclonic and anticyclonic cells. Although it can be shown that solutions of vorticity equation permit the inclusion of these characteristic features of flow pattern in the atmosphere, the interaction between jet streams and planetary waves has not been studied. The objective of this note is to give a systematic account of the motion of planetary waves in a zonal current with jet streams, linear velocity-shear, and with uniform angular velocity.

Planetary wave motion in a zonal current with jet streams—If the vertical velocity is neglected and zero horizontal divergence is assumed, the vorticity equation of an autobarotropic atmosphere is

$$\left(\frac{\partial}{\partial t} - \frac{\partial \psi}{\partial y}\frac{\partial}{\partial x} + \frac{\partial \psi}{\partial x}\frac{\partial}{\partial y} - \nu\nabla^2\right)\nabla^2\psi + \beta\frac{\partial \psi}{\partial x} = 0 \quad (1)$$

where x and y are the Cartesian coordinates, positive toward the east and north respectively; ψ is the stream function, ν the coefficient of kinematic viscosity; ∇^2 is two dimensional Laplacian; $\beta = 2\Omega a^{-1} \cos \psi$ where Ω is the angular velocity of the Earth, a is the radius of the Earth, and φ is the latitude.

It can be shown that the following stream function

$$\psi = -U(t)y + \left\{A \sin\frac{2\pi}{D} y + B \sin\frac{2\pi}{L} \cdot \left[x - \int c(t)\,dt\right] \sin\frac{2\pi}{l} y\right\} e^{-\nu\frac{4\pi^2}{D^2}t} \quad (2)$$

satisfies the vorticity equation (1), provided that

$$1/D^2 = 1/L^2 + 1/l^2 \quad (3)$$

and

$$c(t) = U(t) - \beta D^2/4\pi^2 \quad (4)$$

where D is twice the width of the jet stream; L and l are respectively the wave length and twice the lateral extent of the planetary waves; $c(t)$ is the phase velocity of the wave; $U(t)$ is uniform part of the zonal velocity; A and B are respectively the amplitude of the jet stream and the planetary waves.

Partial differentiation of (2) with respect to $-y$ gives zonal component of the velocity,

---

* In memoriam of Dr. Carl-Gustaf Rossby. Contribution from Meteorology Department, University of California at Los Angeles, No. 35.

$$u = U(t) - 2\pi\left\{\frac{A}{D}\cos\frac{2\pi}{D}y + \frac{B}{l}\sin\frac{2\pi}{L}\right.$$

$$\left.\cdot\left[x - \int c(t)\,dt\right]\cos\frac{2\pi}{l}y\right\}e^{-\nu\frac{4\pi^2}{D^2}t} \qquad (5)$$

It is to be noted that stream function (2) contains the following characteristic features of the field of motion in the atmosphere: (1) one or several jet streams with width $\frac{1}{2}D$; (2) a zonal current of uniform velocity $U(t)$ which is an arbitrary function of time; (3) planetary wave of finite amplitude with wave length L, and lateral extent $\frac{1}{2}l$; (4) cyclonic and anticyclonic cells.

A schematic diagram showing the distribution of streamlines of planetary waves, cyclonic and anticyclonic cells in relation to a jet stream is shown in Figure 1. Notice that on one side of the jet stream is a row of cyclonic cells, on another side a row of anticyclonic cells which, to some extent, resembles the flow pattern in the upper level.

Some interesting information may be obtained from relationships (3) and (4). It is seen from (3) that

$$D < L, l$$

which means that the width of jet stream is always smaller than half the wave length and the lateral extent of the planetary waves. Eq. (2) represents the quasi-stationary solution in which D, l, L are constants, and cannot be applied to transient situations. However, if one applies it to the quasi-stationary situations before and after a period of transition, one may infer from (3) that the increase or decrease of the dimension (lL) of the planetary waves follows respectively the broadening or narrowing of the width of the jet stream and vice versa. It is seen from (4) that the increase or decrease of the phase velocity of the planetary wave in a zonal current with jet stream depends respectively on the increase or decrease of the mean velocity of the zonal current, and depends respectively on the narrowing or broadening of the jet stream. It is worth noticing that the phase velocity of the planetary is independent of the intensity of the jet stream and the effect of friction is to damp out all waves in the current.

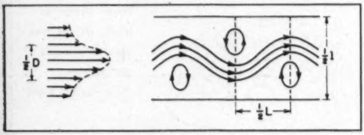

FIG. 1 – Stream-line pattern in a zonal current with jet stream

Planetary-wave motion in a zonal current with linear velocity-shear—For a rotating Couette flow with velocity shear S with respect to y, it can be shown that stream function

$$\psi = -U(t)y - \tfrac{1}{2}Sy^2 - \frac{AL^2}{4\pi^2[1 + (St + \xi)^2]}$$

$$\exp\left\{-\nu\frac{4\pi^2}{D^2}[(1 + \xi^2)t + S\xi t^2 + \tfrac{1}{3}S^2t^3]\right\}$$

$$\times \sin\frac{2\pi}{L}\left\{x - \int c(t)\,dt - Syt\right.$$

$$\left. + \frac{\beta L^2}{4\pi^2 S}[\tan^{-1}(St + \xi) - \tan^{-1}\xi] - \xi y - \delta\right\} \qquad (6)$$

satisfies vorticity equation (1). Here ξ^{-1} is the initial slope of the trough and ridge lines of the waves; δ is a constant to be determined by the initial condition. The first term of the right hand side of (6) gives the velocity of the Couette flow with lateral velocity-shear S; the last term gives a sinusoidal wave with an amplitude which varies with time; $(St + \xi)$ is the reciprocal of the slope of the trough and ridge lines with respect to y.

Note that no stationary or quasi-stationary waves are possible to occur in a zonal current with linear velocity shear, since waves in such a system move with a speed

$$c(t) = U(t) + Sy - \frac{\beta L^2}{4\pi^2[1 + (St + \xi)^2]} \qquad (7)$$

which depends not only on the velocity of the Couette flow, wave length, latitude, but also on the instantaneous slope of the trough and ridge lines of the waves. It is readily seen that for waves in an inviscid zonal current with uniform velocity, frequency equation (7) reduces to that of Rossby's wave [*Rossby* and collaborators, 1939]

$$c = U - \beta L^2/4\pi^2$$

Inspection of (6) reveals that the wave velocity and the slope of the trough and ridge lines vary with time. These are two characteristic features of wave motions in a zonal current with a linear velocity shear, whereas there is no change in the wave velocity and the inclination of trough and ridge lines in a zonal current with uniform velocity.

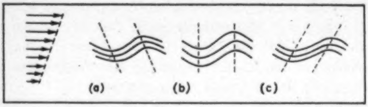

FIG. 2 – Stream-line pattern at different instances in a zonal current with linear velocity-shear

It is readily seen from (6) that waves will eventually disappear in a zonal current with linear velocity shear regardless whether the fluid is viscous or not. However, under certain conditions waves may be amplified within a certain time interval. Waves may be damped, unchanged, or amplified depending respectively on

$$S(St + \xi) + \nu 2\pi^2 L^{-2}[1 + (St + \xi)^2]^2 \gtreqless 0 \qquad (8)$$

For the case that the fluid is inviscid only the term $S(St + \xi)$ remains in (8). Waves will be amplified when the slope of the trough and ridge lines is in the opposite sign to the lateral velocity shear of the zonal current, that is, if $S\,\xi < 0$ and when $t < -S^{-1}\xi$ as shown in Figure 2a. Wave amplitude reaches its maximum when the trough and ridge lines are perpendicular to the zonal current ($t = -S^{-1}\xi$) as shown in Figure 2b, and drops when their slope is of the same sign as the lateral velocity shear as shown in Figure 2c. It is interesting to note that for the inviscid case maximum wave amplitude occurs when the extreme wave velocity is reached. Since the viscosity term in (8) is always positive, viscosity tends to suppress the amplification effect and bring the maximum wave amplitude to an earlier moment than in the case of an inviscid fluid.

Planetary-wave motion in a zonal current on a spherical earth with uniform angular velocity— In order to examine the effect of the curvature of a spherical Earth's surface on the motion of planetary waves let us consider spherical-surface flow of an incompressible viscous fluid with zero velocity divergence. For this case the vorticity equation and equation of continuity are respectively

$$\frac{\partial}{\partial t}\Delta\psi + \frac{1}{a^2 \sin\theta}\left(\frac{\partial\psi}{\partial\theta}\frac{\partial}{\partial\lambda} - \frac{\partial\psi}{\partial\lambda}\frac{\partial}{\partial\theta}\right) \cdot (\Delta\psi + 2\Omega a^2 \cos\theta) = \frac{\nu}{a^2}\Delta^2\psi \qquad (9)$$

$$\frac{\partial}{\partial\theta}(v_\theta \sin\theta) + \frac{\partial v_\lambda}{\partial\lambda} = 0 \qquad (10)$$

where

$$\Delta \equiv \left\{\frac{1}{\sin\theta}\frac{\partial}{\partial\theta}\left(\sin\theta\frac{\partial}{\partial\theta}\right) + \frac{1}{\sin^2\theta}\frac{\partial^2}{\partial\lambda^2}\right\}$$

is the spherical-surface Laplacian operator; θ, λ, a are, respectively, the co-latitude, longitude, and radius of the spherical surface; v_θ and v_λ are, respectively, the velocity components in the directions of the gradients of θ and λ.

It can be shown that the following stream function

$$\psi(\theta, \lambda, t) = -\omega(t)a^2 \cos\theta + \left\{A_n P_n(\cos\theta) + \sum_{m=1}^{n} A_n^m P_n^m(\cos\theta) \times \cos\left[\lambda - \int \Omega_n(t)\, dt + B_n^m\right]\right\} e^{-\nu St} \qquad (11)$$

satisfies the vorticity equation (9). Here $\omega(t)$ is the relative angular velocity of the zonal current which is an arbitrary function of time; A_n and $A_n^m (m = 1, 2, \cdots, n)$ are $n + 1$ amplitude factors, and $B_n^m (m = 1, 2, \cdots, n)$ are n phase angles; $S = (1/a^2)n(n + 1)$ and

$$\Omega_n(t) = [1/n(n+1)]\{(n-1)(n+2)\omega(t) - 2\Omega\} \qquad (12)$$

is the angular phase velocity of the wave which depends on the angular velocity of the Earth Ω, angular velocity of the zonal current $\omega(t)$, and the degree of the surface spherical harmonic n. It is seen from (12) that if the relative angular velocity $\omega(t)$ is absent, the westward wave velocity increases with decreasing wavelength and increasing lateral extent of the waves. It is also seen from (12) that the effect of friction is to damp out the waves. No steady wave is possible in viscous flow over a spherical surface, since this condition would require $S = 0$. However, quasi-stationary waves, which may be defined as waves with zero wave velocity but changing wave amplitudes, may occur if

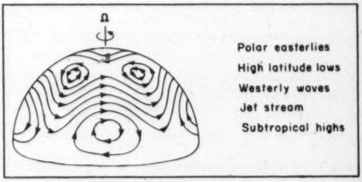

FIG. 3 – Stream-line pattern for quasi-stationary flow over a rotating spherical surface with $m = 4$ and $n = 5$

$$\omega = 2\Omega/(n-1)(n+2)$$

To illustrate the distribution of harmonic waves over a spherical surface, the streamline pattern of an example for the quasi-stationary case with $m = 4$ and $n = 5$ has been sketched in Figure 3. It is interesting to note the resemblance between the streamline pattern in the theoretical model and that in the actual upper level flow in the atmosphere. It is seen from Figure 3 that the streamline pattern consists of major characteristic features in the atmosphere such as subtropical highs, jet stream, westerly waves, high latitude lows, and polar easterlies.

Conclusion—A systematic analysis of planetary waves in a zonal current with jet stream, linear velocity-shear, and uniform angular velocity shows that (1) the phase velocity of the planetary waves in a zonal current with jet stream increases or decreases depends respectively on the narrowing and broadening of the jet stream, (2) the increase or decrease of the dimension of the planetary waves follows respectively the broadening or narrowing of the width of the jet stream, (3) the major effect of a linear velocity shear in a zonal current is to damp out waves in the current, (4) the streamline pattern in a zonal current on a spherical Earth with uniform angular velocity exhibits major characteristic features in the atmosphere such as subtropical highs, jet stream, westerly waves, high latitude lows and polar easterlies, and (5) the effect of viscosity is to damp out all waves in the current.

Microvariations of Water Vapor in the Lower Troposphere with Applications to Long-Range Radio Communications

JOHN R. BAUER AND JAMES H. MEYER

Abstract—Variations of water vapor in the troposphere are calculated from simultaneous airborne measurements of radio refractive index and temperature obtained respectively with a microwave refractometer and an aerograph employing a sensitive bead thermistor. The partial pressure of water vapor is calculated from the well-known equation

$$e(\text{mb}) \cong 2.7(n-1)T^2 - 2.1 \times 10^{-4}PT$$

where n is the refractive index; T is temperature, °K; and P is total atmospheric pressure mb. The method is applied to the investigation of the horizontal and vertical structure of water vapor associated with a thin inversion layer found near 9800 ft pressure altitude. Evidence is offered for the vertical stability and absence of turbulent mixing of the air in the region of the inversion. When the reflection coefficient of the observed layer at radio wave lengths of 600 and 72 cm is computed at a range of 200 mi beyond the horizon, better than an order of magnitude agreement is obtained between the calculated and observed path losses at this range.

EXPERIMENTAL OBSERVATIONS

Introduction—The material presented in this paper is taken from the meteorological research being conducted by the radio propagation group at the MIT Lincoln Laboratory. The objective of this research work is to study the relationships between beyond-the-horizon propagation of meter and centimeter radio waves and the tropospheric weather. The scope of this meteorological research covers both the large- and small-scale variations of the meteorological parameters in the lower troposphere. This report is a study of refractive index, temperature, and calculated water vapor at a particular time and location along the New England coast on August 22, 1956. An Air Force C131-B Convair from Hanscom Field, Bedford, Massachusetts, equipped with an airborne refractometer and an aerograph system, and a Navy P2V from the Naval Air Development Unit, South Weymouth, Massachusetts, equipped with an airborne refractometer, participated in this particular experimental flight. The C131-B and the P2V made simultaneous soundings from 1000 to 10,000 ft pressure altitude at the ends of the predetermined 26.5-mi flight path shown on the map insert Figure 1. Pressure altitude, as used here, represents the quantitative value of the pressure at a given point by giving the height above a given standard pressure at which the pressure occurs in the standard atmosphere. An inversion found at approximately 9800 ft pressure altitude was probed by the C131-B, flying a saw-tooth pattern between 9400 ft and 9900 ft along the flight path from south to north. The saw-tooth pattern was flown for the purpose of exploring the vertical and horizontal distribution of refractive index, temperature, and water vapor associated with the inversion.

A brief description of the parameters measured and the instrumentation used is as follows: The Crain-type airborne refractometer was used to measure the radio refractive index. A Kollsman type KS-4 aerograph system in the C131-B was used to measure temperature, relative humidity, and absolute pressure. Sensitive barometric altimeters were used to measure pressure height. Since the instrumentation is considered capable of measuring microscale variations, the response times and observational errors of these instruments are of interest. An Esterline Angus recorder was used to record relative refractive index as measured by the refractometer. The time required for a complete change of air in the sampling cavity, that is, the 'cleanout time,' has been estimated to be approximately 10^{-2} sec at the operating airspeed of 2.5×10^2 feet/sec. However, since the magnitude of the frequency response of the metering circuit plus the pen recorder was given by the function $A(f) \cong A(0) \exp(-0.67f + 0.035f^2)$, where f is in cycles per second, and $0 < f \gtrsim 10$ cycles/sec, it is clear that refractive index fluctuations containing frequency components in excess of about two cycles/sec were strongly attenuated by the recording circuit. Under ideal flight conditions, the system noise was 0.1 N (an N unit is one part in 10^6 in tropospheric refractive index). Under certain flight conditions such as were some-

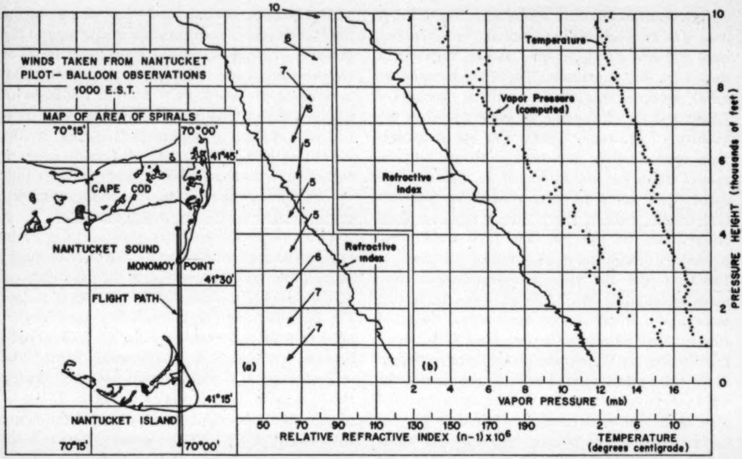

FIG. 1 – Refractive index, temperature, winds, and computed water vapor pressure observed over the Cape Cod and Nantucket, Massachusetts area on August 22, 1956: (a) spiral ascent at Monomoy Point by P2V, 13h 25m–13h 50m EST; (b) spiral ascent over Nantucket by Convair, 13h 25m–13h 50m EST

times encountered during climbing maneuvers, aircraft vibrations produced noise amplitudes as large as 1 N.

The thermister bead employed to measure temperature had a time constant of about four seconds. This time constant (not the temperature recorder) was the limiting factor in measuring temperature fluctuation rates. The noise amplitude in the servomechanism drive for the recorder was approximately 0.1°C. The pressure measuring system consists of an aneroid diaphragm mechanism with a servomechanism for remote indication. This system had a response time of about one second and a probable error of ±0.5 mb.

Calculation of water vapor from refractive index, pressure, and temperature—Since the refractive index measured by the refractometer is relative refractive index, the first step in calculating water vapor from the index data is to find the absolute refractive index. This was accomplished by computing the absolute refractive index from the aerograph temperature, relative humidity and pressure data at some point along the refractive index profile where the index was varying slowly with height. The following formula was used to compute the absolute refractive index at the selected point

$$N \cong (n-1) \times 10^6 \cong 77.6\,P/T + 3.73 \times 10^5 e/T^2 \qquad (1)$$

where P is total pressure in mb, n is radio refractive index, e is partial pressure of water vapor in mb, and T is absolute temperature. Once the absolute values of refractive index are known, the partial pressure of water vapor can be calculated by the formula

$$e \cong 2.68(n-1)T^2 - 2.08 \times 10)^{-1}PT \qquad (2)$$

where the variables are the same as those in the above formula. The temperature and total air pressure used to calculate e were those recorded by the aerograph. Under average summer conditions in the lower troposphere (300°K, 20 mb, water vapor pressure, and 1000 mb, total pressure) the rincemental relationship [*Gerhardt* and *Crain*, 1950] between radio refractive index, water vapor, temperature, and total pressure is given approximately by the relationship

$$\Delta N \cong 4.2\Delta e - 1.4\Delta T + 0.26\Delta P \qquad (3)$$

From this expression it is seen that the contribution of water vapor fluctuations to refractive index fluctuations is sixteen times that due to total air pressure fluctuations.

Flight area and profile measurements—Figure 1 shows the refractive-index profiles obtained from the simultaneous soundings made by the two aircraft. The temperature profile and the calculated water-vapor profile were taken from the C131-B data. The locations for the simultaneous soundings were the end points of the 26.5-mi flight path shown on the map insert. The C131-B made its spiral ascent a few miles south of Nantucket Island and the P2V made its spiral ascent in the vicinity of Monomoy Point. The spiral ascents were approximately five miles in radius, and the rate of climb was 400 ft/min at an indicated airspeed of 150 knots. In order to add more information to the analysis, the Nantucket pilot-balloon observations for the 10h 00m EST winds were plotted. Although the wind sounding was made at 10h 00m and the aircraft measurements were made around 13h 30m, there are some interesting observations which can be made about the wind structure and the aircraft measurements. However, this requires the assumption that little or no change in the wind profile existed between the time of the wind observations and the aircraft measurements. Also, there is an error in height which must be considered between the plotted height of the winds and the height of the aircraft measurements. The winds are plotted for mean sea-level heights and the other data are plotted for pressure heights. The pressure height was on the average 350 ft below the MSL height. Thus, if the plotted winds were shifted 350 ft down the height scale in Fig. 1, one would have approximately the correct fit of the winds to the other data.

Upon comparing the two simultaneous refractive-index profiles in Fig. 1, one can in general make some comparisons of the grosser features of the profiles below 8000 ft. Between 8000 and 1000 ft both the fine and large scale features of the two profiles are poorly correlated. The winds, if one assumes they apply to the data, suggest that there was little shear due to wind speed changes below 8000 ft. However, there is a large rotational change in the wind vector between 5000 ft and 8000 ft. The largest rotation occurs between 7000 and 8000 ft. The attendant rotational shear indicates the possibility of mixing in this height interval. The instability of the temperature lapse rate over a few hundred feet between 7000 and 8000 feet, and the absence of any large discontinuity in the refractive index in this height interval also suggests a well mixed layer of air.

When the assumption is made that the air is horizontally stratified, the temperature profile from the C131-B sounding gives a general over-all picture of the stability of the air sampled between one and 10,000 ft. The air sampled in this height interval was on the average conditionally stable with respect to vertical wind shear. However, the finer features of the temperature profile suggest the presence of many small and rapid fluctuations of temperature where the lapse rates over small increments of height vary from a condition of instability to absolute stability. The most pronounced change in temperature occurs in the vicinity of 9800 ft. The large shelf-type decreases in refractive index above 8000 ft clearly suggest that the phenomena present in this region extended continuously over the entire flight area.

Saw-tooth profiles and cross section—In order to explore the horizontal behavior of refractive index, water vapor, and temperature in the neighborhood of the temperature fluctuation near 9800 ft (see Fig. 1), a saw-tooth flight trajectory was executed between 9400 and 9900 feet along the 26.5-mi path between Nantucket and Monomoy Point. The original refractive index record obtained during this saw-tooth flight is shown in Figure 2. Beginning in the upper right- hand corner of the figure with ascent A we note the sudden fluctuation of refractive index from 219 *N* units to 207 *N* units between 9700 and 9750 ft. On descent B and all subsequent ascents and descents the index fluctuation is clearly present at approximately the same altitude. The small scale fluctuations seen on the ascent profiles but not on the descent profiles are due to communication of aircraft vibrations to the pen of the recorder during the powered climbs.

Figure 3 shows the refractive index, temperature, and calculated water vapor profiles for the individual slant ascents and descents made during the saw-tooth probing of the inversion in the vicinity of 9800 ft. The slanting heavy lines in Figure 4 show the computed flight path of the aircraft during its ascents and descents through the inversion while transversing the 26.5-mi path from south to north. The measurements shown on ascent A in Figure 3 were obtained along the trajectory shown by the first heavy slanting line (A) on the left side of Figure 4. Ascent A was made in the vicinity of Nantucket Island and descent F was made in the vicinity of Monomoy Point. Following the temperature profiles from ascent A through descent F, one may note the fact that the temperature inversion is well defined over the Nantucket area. However, as one moves toward Cape Cod the inversion becomes less sharp in its temperature gradient. Note the small differences in the heights of the moisture shelves among the individual ascents and descents. Following the refractive-index and vapor-pressure profiles through this series of soundings, we observe the rapid fall-off

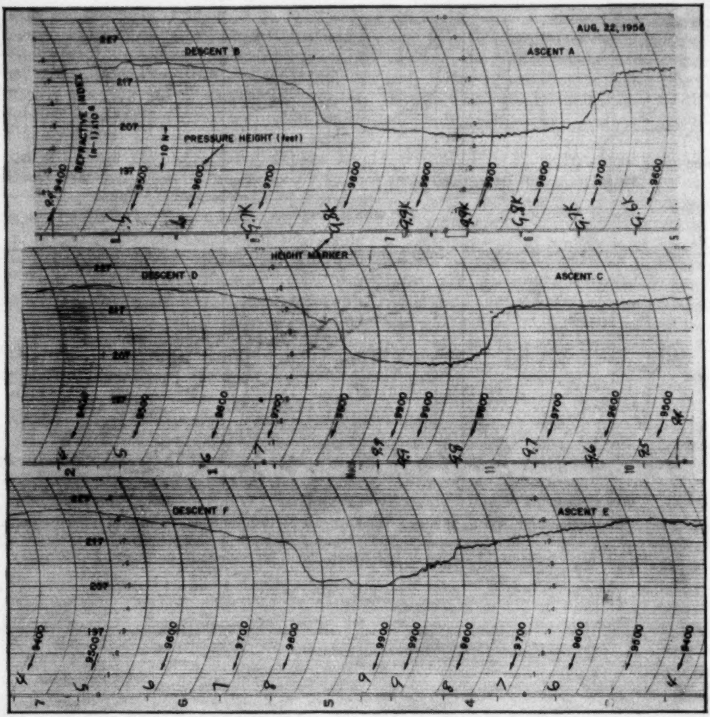

FIG. 2 – Original microwave refractometer record of radio refractive index observed during saw-tooth flight between pressure altitudes of 9400 and 9900 ft between Nantucket Island and Monomoy Point, Massachusetts, on the afternoon of August 22, 1956; note sharply stratified layer near 9800 ft

of both functions when the temperature lapse rate satisfies the condition of absolute stability ($dT/dz > 0$) [*Haurwitz*, 1941]. The total moisture fall-off in all the profiles, with the exception of ascent *E*, is on the order of two millibars, and the changes occur over a height difference on the order of a few meters. The homogeneity of the moisture above and below the inversion is another interesting feature of this data. Above the inversion the moisture remains at 2 ± 0.3 mb over the entire 26.5-mi flight path and below it remains at 4 ± 0.5 mb over this distance.

With respect to beyond-the-horizon propagation of meter and centimeter radio waves, *Gordon* [1955] has associated small scale turbulence with an inversion of this type. The homogeneity of the moisture above and below the inversion is strongly suggestive of the absence of turbulent motion within the layer. It would appear that this suggestion is strengthened by the condition of absolute stability of the temperature gradient across the layer, unless, of course, sufficient wind shear were present to produce turbulent motion. The pilot-balloon wind observations made at Nantucket four hours prior to the aircraft measurements (see wind profile, Fig. 1) indicated a positive wind-speed change of four knots between 9000 and 10,000 ft. If the assumption is made that these wind-speed

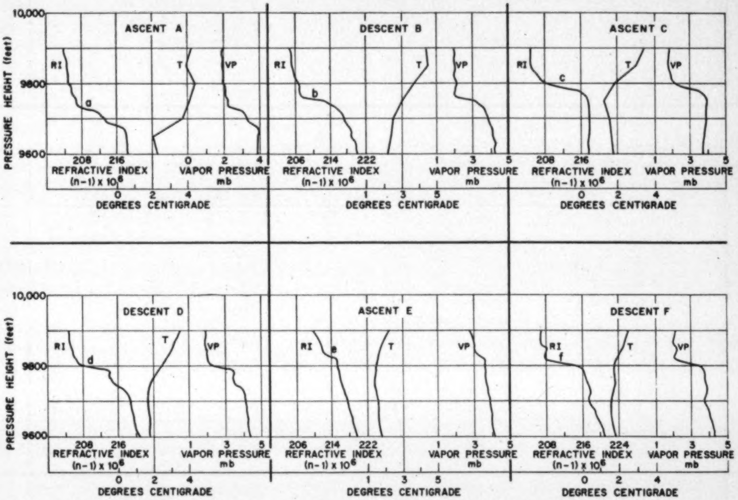

FIG. 3 – Saw-tooth profiles, Nantucket to Monomoy Point, August 22, 1956; individual profiles of refractive index, temperature, and computed water vapor pressure obtained during saw-tooth probing of inversion layer observed near 9800 ft between Nantucket Island and Monomoy Point, Massachusetts, on August 22, 1956

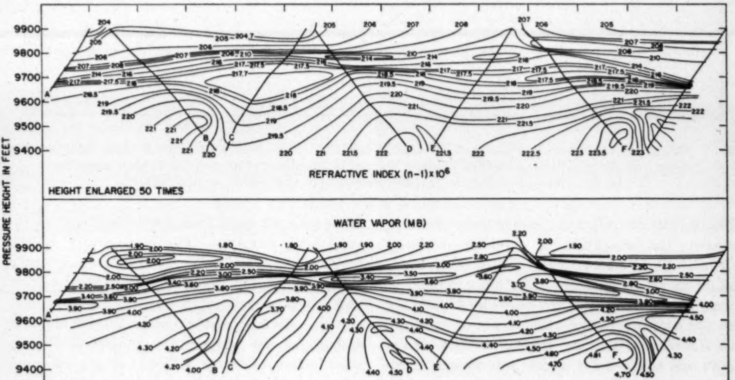

FIG. 4 – Saw-tooth cross sections between 9400 and 9900 ft (pressure altitude) showing contours of refractive index and water vapor pressure in the vicinity of inversion layer observed over 26.5-mi flight path between Nantucket Island and Monomoy Point, Massachusetts, on August 22, 1956

data are applicable at the time of the aircraft measurements, then the calculated values for the Richardson's numbers at the inversion levels of the saw-tooth profiles varied between 18 and 79 with an average of 36. Since Richardson's number need only exceed unity to reduce turbulent flow to laminar motion, these calculations further suggest the absence of turbulence across the inversion [*Sutton*, 1953].

The saw-tooth cross section presented in Fig. 4 is an attempt to show the vertical and horizontal distributions of refractive index and water vapor associated with the inversion between 9400 and 9900 ft over the 26.5-mi flight path. The cross section was made by linearly interpolating between the points of refractive index and water vapor plotted along the flight path with respect to time. The horizontal distance was calculated from time and ground speed of the aircraft. In order to represent the horizontal irregularities, the height scale is enlarged fifty times that of the horizontal scale. If the scale of this cross section were reduced to a one to one scale, the total 500-ft height difference would have to be compressed into a height interval comparable to one-tenth of a 100-ft height increment as shown in Fig. 4. Because of the close packing of the contours in the vicinity of the inversion, difficulty was experienced in trying to draw in all the one N-unit lines of equal refractive index and the 0.2 mb lines of equal vapor pressure. Therefore, many of the contour lines had to be omitted. However, if one notes the changes in the density of the contour lines of refractive index and water vapor, he can easily see the rapid fall-off of both functions with height. An important consideration to be made about this cross section is its resolution. The resolution of the data is better where the flight paths of the individual ascents and descents are close together. The resolution of this cross section could have been improved considerably by making one or two horizontal flights over the flight path at different altitudes between 9400 and 9900 ft. In future flights of this type, horizontal flights are planned to improve the resolution of the data. Upon relating the temperature profile of ascent E in Figure 3 with the horizontal and vertical distribution of refractive index and water vapor in the vicinity of ascent E in Fig. 4, one can see why the refractive index and moisture changes across the layer on the particular ascent were not as large as in the other profiles. The effect is clearly associated with the reduced temperature change at the inversion level. The contours in the vicinity of this temperature change suggest that some form of a disturbance was affecting the inversion at this particular location along the flight path. However, because of the limited quantity of data there is no positive identification for the type of disturbance which was present.

APPLICATIONS TO RADIO COMMUNICATIONS

Radio reflections from an idealized layer—Average yearly radio field intensities at wave lengths from a few centimeters to several meters at ranges from a few tens to several hundred miles beyond the horizon are tens to hundreds of decibels higher than can be accounted for on the basis of diffraction round the curved Earth [*Institute of Radio Engineers*, 1955]. The propagation is believed to arise principally from scattering by some type of dielectric inhomogeneity in the troposphere (0–10 km) or stratosphere (10–25 km) or both. *Booker* and *Gordon* [1950] have proposed that omnipresent isotropic turbulent eddies in the atmosphere scatter radiation beyond the horizon, while *Carroll* and *Ring* [1955] maintain that the main effect is due to a type of mode propagation through the smoothly tapered thick atmosphere.

Some years ago, *Smyth* and *Trolese* [1947] and *Saxton* and others [1951] showed that layers below 4000 ft reflected waves a few meters long to distances up to 92 mi beyond the horizon. More recently *Bauer* [1956] described refractometer measurements of extremely thin and distinct reflecting layers up to heights of three km in the lower troposphere which he estimated are capable of explaining the propagation of wave lengths from a few centimeters to several meters to distances up to 200 mi into the 'scatter zone.' The remainder of this paper is devoted to the question of the partial reflection potential of the stratified irregularity described.

Deferring for a moment the presence of horizontal irregularities in the layer shown in Figures 3 and 4, that is, assuming the layer is perfectly plane stratified, note that the variations with height z of refractive index across the profiles of the layer are rather well approximated by the function

$$n(z) = \frac{n_1 + n_2}{2} - \left(\frac{n_1 - n_2}{2}\right) \times \tanh\left(\frac{2z}{l}\right) \quad (4)$$

for which layer model the exact reflection coefficient was first worked out by *Epstein* [1930]. n_1 and n_2 are the refractive indices of the air just below and just above the layer, respectively. The origin of z is taken at the height of maximum gradient of the

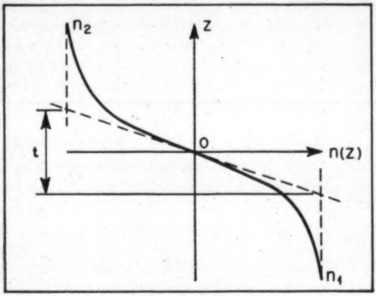

FIG. 5 – The refractive index model employed in computing the radio reflection from an elevated layer

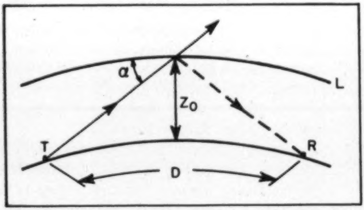

FIG. 6 – The geometry of single reflection from a layer to a receiving antenna *R* beyond the horizon

transition layer; the layer thickness t is defined as the difference in the heights of the intersections of the tangent to $n(z)$ at the middle of the layer and the index levels n_1 and n_2 (see Fig. 5). Let α be the glancing angle of incidence of a radio wave on the layer as shown in Fig. 6. For those relatively large values of α which characterize long propagation paths $\alpha^2 \gg 2(n_1 - n_2)$ [*Bauer*, 1956]. For this condition, most of the incident energy is transmitted through the layer and only a weak reflection is allowed. *Bauer* [1956] has shown that the power reflection coefficient ρ for the model we have chosen (Eq. 4) is given by

$$\rho \cong \left(\frac{n_1 - n_2}{2\alpha^2}\right)^2 \left(\frac{\pi m}{4}\right)^2 \left[\sinh\left(\frac{\pi m}{4}\right)\right]^{-2} \qquad (5)$$

where $0 \leq m = t/t_0 = \dfrac{4\pi\alpha t}{\lambda_0} \lesssim 1$, and λ_0 is wave length of the incident radio wave. Measurements made at Lincoln Laboratory, MIT, by *Chisholm* and others [1957] at a range of 188 mi with $\lambda_0 = 72$ cm show a yearly average path loss of about 62 db below free space, while *Abel's* [1956] airborne measurements at $\lambda_0 = 6$ m show a mean path loss of 45 db below free space at a range of 200 mi. From Figure 3 we take $n_1 - n_2 \sim 10^{-5}$, $t \sim 10$ m. Let the mean layer height be 9800 ft. When the correction for standard refraction below the layer is made, we find $\alpha \cong 2.8 \times 10^{-2}$ radians for the 200-mi range. From (5) we obtain a reflection coefficient of 4×10^{-5} at $\lambda_0 = 6$ m and 1×10^{-6} at $\lambda_0 = 72$ cm. These reflection coefficients predict path losses of 44 db and 60 db below free space for the 600 and 72 cm wave lengths, respectively, in close agreement with the observed path losses. In the microwave region, the 10-m thick layer described here is far too thick to account for the observed propagation to 200 mi; a layer no more than two meters thick is required [*Bauer*, 1956]. Evidence for the existence of such thin layers has been previously reported [*Bauer*, 1956].

Discussion of horizontal irregularities and layer size—The central theoretical difficulty associated with layer theory is the effect of horizontal irregularities in the dielectric structure, vis., horizontal changes in layer height, thickness, $n_1 - n_2$, etc. Such variations are clearly seen in Fig. 3. According to Rayleigh's criterion [*Kerr*, 1951] a surface may be considered a plane specular reflector when the unevenness Δh does not exceed approximately $\pm\lambda_0/(4\pi \sin\alpha)$ over a Fresnel zone. For our example of propagation to 200 mi via a 9800-ft layer, this criterion requires that the unevenness at 600 and 72 cm should not be much larger than ±55 ft and ±6 ft, respectively. The Fresnel zone for our example (range $D = 200$ mi, $\alpha = 2.8 \times 10^{-2}$ radians) is an elliptically shaped patch of length $l \geq (D\lambda_0)^{1/2}/2\alpha$ and width $w \geq l\alpha$ [*Bauer*, 1956]. For $\lambda_0 = 72$ cm, the required dimensions w and l are 0.15 and 5.3 mi, respectively, while for $\lambda_0 = 6$ m, w and l must be 0.43 and 15 mi, respectively. A study of Figures 3 and 4 shows that the center of the layer (height of maximum index gradient) varies smoothly by about ±50 ft over a horizontal distance of 26 mi. Thus the entire layer appears to satisfy the Rayleigh criterion for $\lambda_0 = 6$ m. While the resolution of the data is insufficient to determine the height variations required for the 72-cm wave reflections, the linear interpolations of Figure 4 strongly suggest the presence of several smooth patches a few miles long which are smooth enough to reflect at this wave length. At both wave lengths, however, the layer must be considered a slightly warped reflector which could hardly be expected to support a good image.

In conclusion we emphasize that insufficient meteorological and radio data are available to establish the extent to which stratified layers support long-range short-wave communications through the troposphere. Available airborne meteorological data indicate that during good flying weather there are almost always some stratified layers in the troposphere. During very cold, dry, or unstable weather, scattering from poorly stratified or somewhat isotropic irregularities may play an important role in tropospheric short wave radio propagation well beyond the horizon.

Acknowledgments—The authors wish to extend their sincere appreciation to J. H. Chisholm, MIT Lincoln Laboratory, for his continuing interest, encouragement and advice; to J. M. Austin, MIT, and R. Cunningham, GRD, for their helpful comments; to Fred Spatola, GRD, for his advice relating to the aerograph instrumentation; to the flying personnel of the 6521st Test Support Squadron, Hanscom Field, Bedford, Massachusetts, and the Naval Air Development Unit, South Weymouth, Massachusetts, for their cooperation; and to Florence A. Wilson for reducing much of the experimental data. The research reported in this document was supported jointly by the Army, Navy, and Air Force under contract with the Massachusetts Institute of Technology.

A Theoretical Analysis of Sea-Ice Strength

DON L. ANDERSON AND WILFORD F. WEEKS

Abstract—For the first time an attempt is made to derive a theoretical relationship between sea-ice strength and the controlling factors of salinity, temperature, and density. A geometric model of the ice-brine relationship is constructed from photographs and used to calculate tensile strength of warm (above −20°C) sea ice. The theoretical results compare well with experimental data. The model developed can be extended to colder temperatures by considering the effect of solid salts.

Background—When sea water freezes, small flat plates of pure ice form, leaving behind a concentrated brine which tends to drain out of the ice. However, a certain amount of the brine is retained between the ice plates in layers or pockets, causing the sea ice as a whole to be salty. In general, the faster the ice grows, the more brine is trapped. When the ice first forms, the flat ice plates float on the surface of the water with their c axes vertical, forming a very weak, highly saline mush of overlapping plates. As the ice thickens the plates grow at an angle to the surface, and, at about 1.5 cm from the top, depending on the freezing conditions, vertical plates, with the c axes horizontal, predominate. In lake ice, on the other hand, the c axis often remains vertical throughout the thickness of the ice, and long, candle-shaped crystals are formed. The small plates alternating with layers of brine occur in bundles which appear as single crystals under crossed polaroids.

The temperature and salinity of the ice determine the amount of brine and hence the thickness of the brine layers. The salinity of the brine is much greater than that of the original sea water and depends on the temperature of the surrounding ice with which it is in thermal equilibrium. As the sea ice becomes colder, more ice freezes out of the brine, which becomes more concentrated. With a temperature rise, ice melts and the brine becomes diluted. These brine layers shrink as the temperature decreases and finally 'neck' and separate into vertical cylinders which often extend entirely through the ice sheet. These brine cylinders are separated by ice 'bridges' which connect the original plates. The separation of the layer is controlled predominantly by surface tension. The cylinders are therefore circular or elliptical in horizontal section. The process of the brine-layer separation into cylinders is shown diagrammatically in Figure 1. The hatched area is brine.

Figure 1a is a horizontal section (plan view) showing ice plates separated by brine layers. In Figure 1b the brine layers have begun to 'neck,' and in 1c the brine layer has separated into cylinders. Figure 1d shows the orientation of elliptical cylinders—the short axis of the ellipse is always perpendicular to the ice plates. With a further temperature drop the radii of the cylinders decrease. In the case of elliptical cylinders the long axis shrinks faster than the short, and the cross section approaches a circle. Figure 2a is a photograph of a horizontal section of sea ice in which the layers have begun to 'neck.' In Figure 1c and 2b the layers have split into rows of cylinders. Figure 2d is a vertical section of the same ice. Note the length of the brine pockets. Figure 1f is a three-dimensional schematic sketch of the ice-brine relationship. Fig. 2c shows badly deteriorated ice.

Ideally, a row of equally spaced, equal-diameter, circular cylinders will be formed. Actually, ellipses are more common, and spacing and dimensions vary widely. Often the brine layer splits into two or more parallel rows of cylinders. The possible complexity of the broken brine layer is evident in the photographs.

These cylinders stay long in relation to their diameter because of gravity and the thermal gradient across the ice. They are unstable and migrate to the warmer temperature, which in winter is the lower surface of the ice [see *Veinberg*, 1940]. This causes brine to drain out of the ice even under very cold conditions. The salinity of the ice therefore decreases from its initial value of 15 to 20‰ to about 5‰ late in the first season. The various constituents of the brine crystallize out as their eutectic point is exceeded. Sea ice probably never becomes completely solid under natural conditions. The presence and geometry of these brine pockets are the controlling factors in the strength of the sea ice. The present analysis is limited to warm ice. No attempt is made to determine the quantitative effect of solid salts.

When sea ice breaks in tension or flexure, it

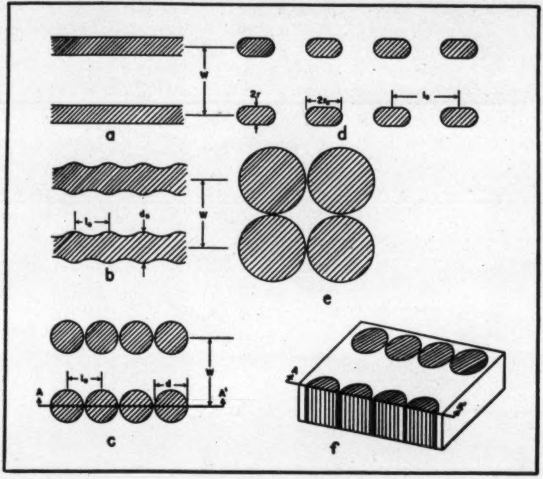

FIG. 1 – Schematic diagrams showing how a brine layer splits into cylinders; see text for details

breaks primarily along these brine cells, parallel to the small plates. Figure 3 is a rubbing of a horizontal section of an ice beam that has been broken. The parallel lines are the edges of single plates. Each group of parallel lines is a crystal. Sea-ice failure surfaces are usually irregular because of this tendency to break along the plate boundaries.

Sea-ice model—To derive a theoretical relationship between strength and the controlling factors of salinity and temperature, we shall use the above information to construct a simplified model. We will consider the strength in tension since a loaded ice sheet usually fails in tension.

Consider a small, thin slab of sea ice in which the brine cylinders go all the way through. In Figure 1c let A–A' be the line of break. The direction of tension was at right angles to this line. The strength of the ice depends on the area of the cross section normal to the tension. Because of the presence of the brine the effective cross-sectional area is reduced.

Let $\beta_e = d/l_o$ where β_e is the amount of brine in a unit area of the failure plane, d is the diameter of the cylinders, and l_o is the cylinder separation in the failure plane (Fig. 1). The effective width of the area is then $(1 - \beta_e)$, considering unit thickness. In the case of ellipses, $\beta_e \cong 2r_e/l_o$.

The strength of the sea ice σ then will be a function of the form

$$\sigma \sim \sigma_p\,(1 - \beta_e) \tag{1}$$

where σ_p is the strength of the ice with no brine cells, that is, pure ice.

The brine cells also act as stress concentrators. The highest stress will be on the edge of the cylinder normal to the direction of tension, and this will be the point of initial failure. A single, round, cylindrical hole in an infinite plate will have a tangential stress on its boundary equal to three times the applied stress. An elliptical hole with its long axis normal to the tension will have an even larger stress concentration [see, for instance, *Timoshenko*, 1934]. The failure surface will spread perpendicular to the direction of tension—in this case, along the row of holes. The apparent strength of a slab in the vicinity of a hole is one third of the strength with no hole. Actually, with only a few holes the strength may not be reduced to this extent except under repeated loadings. The crack will spread slightly with each loading, and finally the slab will fail by fatigue. With the numerous 'flaws' in sea ice, however, the cracks intersect, and we may consider that the strength under single loading is immediately reduced.

The stress-concentration factor k is defined as

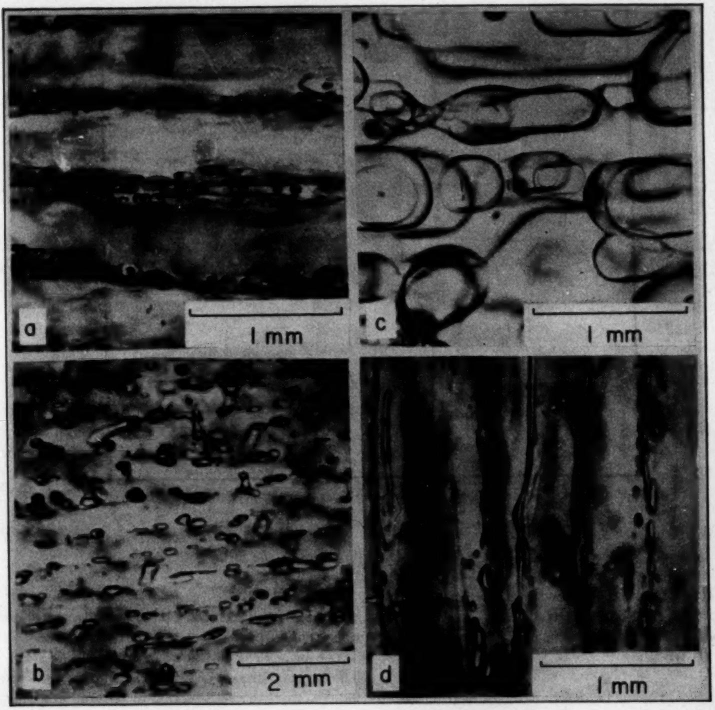

FIG. 2 – Photomicrographs of sea ice, showing brine-ice relationship

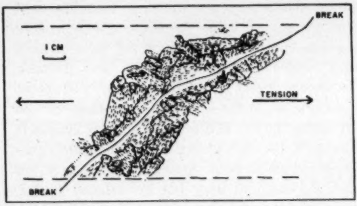

FIG. 3 – Rubbing of a broken segment of sea ice

the ratio of the maximum stress to the average stress in the minimum section. The stress in the minimum section is the force on the end of the slab divided by the effective cross-section area.

Thus, considering the ice at its breaking point

$$k = \sigma_p(1 - \beta_e)/\sigma \qquad (2)$$

This puts the strength equation in the form

$$\sigma = \sigma_p(1 - \beta_e)/k \qquad (3)$$

When the ice is very cold and the brine pockets are small and far apart, we have essentially isolated holes in an infinite plate. As the ice warms and the brine pockets become larger and their edges closer together, the stress concentration factor decreases rapidly. There are, however, usually many small brine pockets scattered between the large ones; these are remnants of the brine that went to form the large cylinders. These small cylinders are effective stress concentrators and will always have a stress concentration at their boundary of approximately three. The relation between strength and β_e is shown in Figure 4 for a row of equally

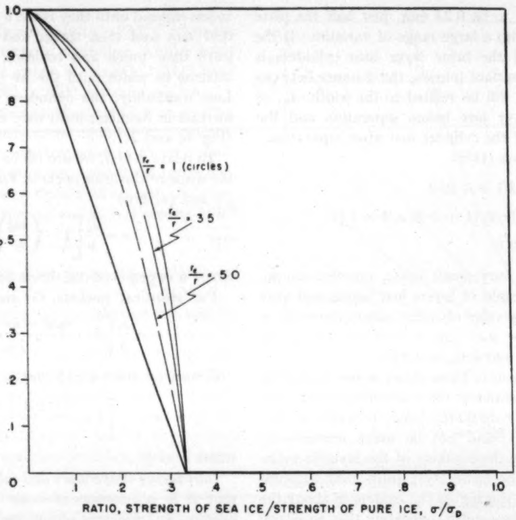

FIG. 4 – The effect on the strength of the amount of brine (β_e) and brine orientation along the failure plane

spaced circles and also for a row of ellipses with different axis ratios. The curves, for the most part, are sketched from experimental data of *Frocht* [1935] and Capper [*Howland*, 1935] and a theoretical solution by *Howland* [1935].

As the long axis of the ellipse increases, the curves approach the straight line which represents a constant stress concentration of three, the case where there are always small 'remnant' cylinders. This straight line gives the minimum strength at all times; the curve representing the row of circles gives the maximum. Since the ice will break where the strength is minimum, we shall use the straight line which represents a constant stress concentration of three. The curves all approach 0.33 on the abscissa because with a small brine content the brine pockets are mostly circular.

The slopes of the curves are discontinuous at $\beta_e = 0$ and jump to the strength of pure ice. As β_e approaches unity, the strength goes to zero. When β_e is small but the ice is still warmer than approximately −20°C, the strength is one-third that of pure ice. In very cold ice this strength reduction appears only upon repeated loading, as mentioned above. Note that lake ice is not necessarily 'pure' ice because of the presence of minute flaws.

Other factors tend to depress the strength value from the ideal row of circular holes. Unequal spacing, varying diameters, and irregular shapes will all increase the stress concentration and decrease the effective cross-sectional area.

Measurements from photographs—If l_0, the brine pocket separation, has a relation to W, the plate width, or if W is constant, then β_e can be related to β, the brine content by volume, of the ice. From about 50 measurements on photographs of sea ice under many conditions from a variety of locations, W was determined to be 0.46 mm with a small deviation from this value. Several measurements by *Fukutomi* and others [1952] show an average value of 0.39 mm. *Nakaya* [1956] describes a layer structure in pure ice crystals revealed by Tyndall figures. He determines the mean width of these plates to be 0.5 mm. Apparently the plates forming sea-ice crystals are equivalent to the plates in pure ice, but because of the brine layers the plate structure in sea ice is much more evident. This also suggests that impurities cause the plate structure in 'pure' ice.

A similar number of measurements from photographs of brine layers which have broken into round cylinders show the average distance between cylinders, l_o, to be 0.23 mm, just half the plate width, but with a large range of variation. If the separation of the brine layer into cylinders is governed by surface tension, the distance between the cylinders will be related to the width, d_o, of the brine layer just before separation and the diameter d of the cylinder just after separation.

From *Nakaya* [1956]

$$d/d_o = 2(1 + \epsilon) \cong 2$$

$$l_o/d = (\pi/2)\ (1 + \epsilon) \cong \pi/2 = 1.57$$

$$\therefore\ d_o/l_o \cong 0.32$$

where ϵ is a very small value, not determined. From photographs of layers just before and after splitting, an average of many values shows d_o = 0.07 mm, l_o = 0.23 mm, d = 0.136 mm, giving $d_o/l_o = 0.30$, and $d/d_o = 1.94$.

The agreement of these ratios seems to indicate that surface tension is the controlling factor. This agreement is remarkably good, considering that measurements could not be made immediately before or after the breaking of the layer in cylinders. When the brine layer splits into elliptical cylinders, the spacing of the centers is about the same as the plate width, indicating that an ellipse is simply two joined circles. As the ellipses shrink, they may break again. When a brine layer splits into ellipses, the short dimension $2r$ stays about 0.07 mm.

Converting to brine content—The brine content β of the ice is the ratio of the volume of the brine to the total volume. In the case of round cylinders

$$\beta = \tfrac{1}{4}\pi d^2/l_oW = \pi d^2/4a\, l_o^2 = \pi\beta_e^2/4a \qquad (4)$$

where $a = W/l_o$.

For 'elliptical' cylinders [not true ellipses]

$$\beta = \{\tfrac{1}{4}\pi(2r)^2 + (2r_e - 2r)(2r)\}/l_0W$$

$$= \frac{\pi r^2 + (\beta_e l_0 - 2r)(2r)}{al_0^2} \qquad (5)$$

Just before the layer breaks into cylinders $\beta = d_o/W \cong 0.07/0.46 \cong 15.2$ pct by volume.

This indicates that ice with more than about 15.2 pct by volume of brine has no strength. This no-strength condition is the skeleton layer phenomenon mentioned by *Weeks* and *Anderson* [1958]. The skeleton layer, then, has a brine content of at least 15.2 pct by volume. This high brine content on the bottom of the sheet is due to high salinity caused by brine drainage and the high temperature of the underlying water.

When very cold ice is warmed, the brine cylinders expand until they reach a diameter of about 0.07 mm and then spread out along the plates until they touch and coalesce. The layers then increase in width until the ice is entirely melted. Less commonly, the cylinders stay circular and increase in diameter until they touch and coalesce (Fig. 1e and 2c).

To relate σ to β, we use (4) or (5), depending on the shape of the brine pockets. For circular pockets, (3) and (4) give

$$\sigma = \frac{\sigma_p}{k}\left[1 - \left(\frac{4a\beta}{\pi}\right)^{\frac{1}{2}}\right] \qquad (6)$$

where a depends on the brine-pocket separation.

For 'elliptical' pockets, (3) and (5) give

$$\sigma = \frac{\sigma_p}{k}\left[1 - \frac{al_0^2\beta - \pi r^2 + 4r^2}{2rl_0}\right] \qquad (7)$$

Since l_o, r, and a are all measured, this reduces to

$$\sigma = \frac{\sigma_p}{k}\left[1 - \frac{0.2116\beta + 0.0011}{0.0322}\right] \qquad (8)$$

where $a = 1$.

Introducing temperature and salinity—Brine content β is a function of both temperature and salinity. In m grams of sea ice of salinity S_i‰, there are n grams of brine of salinity S_b‰ [*Malmgren*, 1927].

$$n/m = S_i/S_b \qquad (9)$$

where $n/m = \beta_w$ (pct brine content by weight). This formula holds until solid salts begin to pre-

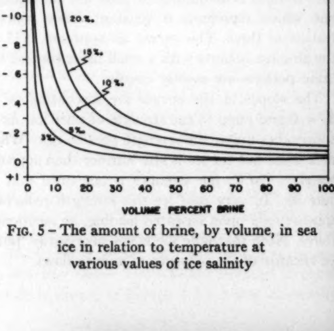

FIG. 5 – The amount of brine, by volume, in sea ice in relation to temperature at various values of ice salinity

cipitate. It is fairly accurate to −22.9°C when the sodium chloride starts to crystallize. At this point approximately 3.2 grams of $Na_2SO_4 \cdot 10H_2O$ have already precipitated in 1000 grams of sea ice.

With every S_b there is associated a temperature, because of previously noted equilibrium considerations; and with every temperature there is associated a density of pure ice, a density of brine, and, combining the two, a density of sea ice.

The relation between β and β_w is [*Veinberg*, 1940]

$$\beta = d_i \beta_w / d_b \tag{10}$$

where d_i = density of sea ice, and d_b = density of brine.

Therefore, knowing the temperature and salinity of the ice we can determine the brine content by volume, which we have already related to strength. Brine content by volume is plotted against temperature for various salinities in Figure 5. A more accurate curve, taking into account solid salts, has recently been developed by one of the authors (unpublished manuscript by DLA, Some Properties of Sea Ice).

The only quantity now lacking in (7) and (8) is the strength of pure ice. The best experimental values for the tensile strength of pure ice were obtained by *Butkovich* [1954]. His values for the relation of tensile strength of pure ice to temperature are essentially the same as those of *Wilson* and *Horeth* [1948] in flexure. Butkovich's values are used as the starting points in our curves, although they must be considered as only a first approximation to the actual strength of the small ice bridges. Butkovich's values are not obtained from perfectly pure ice and we also know that very small volumes give a higher strength than larger volumes. We can, however, obtain relative strengths by using these values. Pure ice may be up to three times as strong as reported by Butkovich.

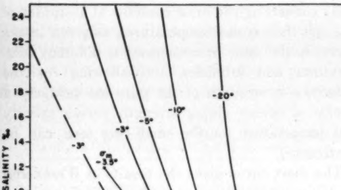

FIG. 6 – The relation between tensile strength and salinity at various temperatures for circular splitting of the two different cylinder spacings

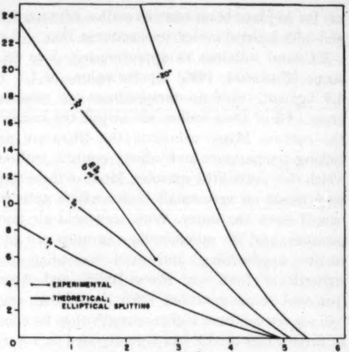

FIG. 7 – The relation between tensile strength and salinity at various temperatures for elliptical splitting

Values for strength versus temperature and salinity are plotted in Figures 6 and 7. Figure 6 assumes that the brine pockets enlarge as circular cylinders until they coalesce. Two different cylinder spacings are plotted for $t = -3$°C. The lower dashed curve is for $a = 2$; the solid curves for $a = 1$. The short curve shows experimental data [*Weeks* and *Anderson*, 1958]. Figure 7 assumes that the cylinders remain circular until $d = 0.07$ mm and then expand as ellipses. This happens when β is 3.6 pct. Spacing does not appreciably change the curves in this latter figure. As stated before, the ellipses are more common, and, since they cause lower strength, they would be expected to be especially common along the line of break. The value of k is assumed to be a constant three in the two preceding curves. The short curve is from the experimental data. In the experimental analysis the average temperature of the entire ice sheet was used. The beam tests are not directly comparable with theoretical results in tension. The result of stress concentration at the end of the cantilever has been ignored, and a constant cross section has been assumed in the experimental work.

Other investigators—Butkovich [1956] reports values for in-place beam tests on sea ice between 2.21 and 3.98 kg/cm² for ice temperatures from −5 to −8°C and salinities of approximately 5 to 8‰. Assur [*Butkovich*, 1956] reports values of 1.1 to 4.9 kg/cm², with no temperatures or salinities given. All of these values are within the areas of the curves. Many values in the literature are lacking temperature and salinity control, without which they have little meaning. Most of these tests were made on very small beams which were removed from the water. With very cold air temperatures and low salinities these samples can give results approaching and even exceeding the strength of fresh ice. *Petrov* [1955] and Assur (personal communication, 1956) report that very cold sea ice can have higher strength than lake ice. In these cases the ice has been exposed to a very cold air temperature, and the solid salts act as binders rather than stress concentrators. The warm underside of the ice is the point of initial failure under most conditions in situ. In the ice sheet the majority of the ice never experiences extreme cold because of the presence of the warm water. Also the different orientation of the crystals in sea ice would affect the strength.

Butkovich [1956] also reports results of small-ring tensile tests on sea ice. These values show a greater strength than the in-place tests reported by him and are also higher than the present writers' values. The small-ring tensile tests cause a break parallel to the applied force and extending between the points of application of the force. The break, then, is forced to cross crystal and plate boundaries, causing a much higher apparent strength. A statistical study of the plate size and orientation would permit a maximum, minimum, and average strength to be calculated, using the theory developed in this paper. Also, other type strength tests may be approached similarly.

Small beam tests seem to give values approximately 2.6 times greater than in-place cantilevers. Ring tests give results up to four times higher.

Even if the results of the two methods of testing are not at present directly comparable, they should give a similar strength, temperature, and salinity relationship. Butkovich performed 137 ring tests under a variety of temperatures and a small range of salinities, making them very valuable for giving the temperature dependency of the strength of sea ice. Plotting temperature versus strength for his ring tests for a constant salinity of 5‰ gives us the curve to the right in Figure 8. Each point is an average of about ten values. The curve indicates that, for a decreasing temperature, strength increases rapidly at first and then more slowly. The theoretical results (curve at left) show a similar tendency and compare reasonably well, remembering that we are not comparing values of strength but changes in strength with temperature. The inflection point for both curves is about −5°C. Extrapolating the experimental curve to no strength gives us, very roughly, 11 pct brine by volume (Fig. 5).

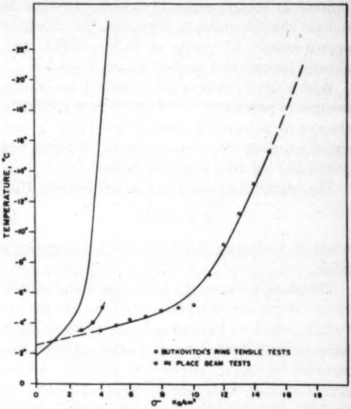

FIG. 8 – Relation between temperature and strength for sea ice of a salinity of 5‰; the solid curve is theoretical, elliptical splitting

By converting the brine contents at a salinity of 5‰ and the various temperatures, as given in the curve, to the same brine content at different temperatures and salinities, and allowing for the difference in strength of the pure ice 'bridges,' a family of curves giving strength versus salinity and temperature for the small-ring tests can be constructed.

The short curve gives the results of *Weeks* and *Anderson* [1958]. Because of the limited temperature range available in thin, in-place beams, this curve is very rough, but it extrapolates to about the same brine content at no strength as predicted in the theory.

Effect of enclosed air—The air content of sea ice can be very considerable. The air bubbles tend to concentrate in the brine pockets, and they have approximately the same effect on strength as adding a similar amount, by volume, of brine. Ice that has formed very rapidly under very cold conditions, or ice that has formed under turbulent conditions, is especially able to trap a large amount of air. Therefore, most of the air in young ice is near the top. As ice ages, the brine drains out and is largely replaced by air, giving old ice a considerable air content throughout its thickness.

The air content is reflected in the density. As stated before, the temperature and salinity completely define the density of air-free ice. The difference between measured and computed density is due to air. The air content can simply be added to the brine content when roughly calculating the strength of sea ice.

The density of warm sea ice can be obtained from (9) and (10).

$$d_i = \beta d_b S_b/S_i \tag{11}$$

Values of sea-ice density are published in *Malmgren* [1927], *Sverdrup* and others [1942], *Zubov* [1945], *Veinberg* [1940], and *Dorsey* [1940], as well as in some standard engineering and oceanographic tables.

In a sample computation for ice of 5‰ salinity and temperature of −7°C, the density is determined to be 0.925. If the measured density is, for instance, 0.920, then 0.005 grams of brine per cubic centimeter of ice have been replaced by air and we must add $(0.005/d_b \times 100)$ pct to the brine content obtained from the measured salinity and temperature. This calculation will also take into account original air. Because of the inherent inaccuracies of measuring density, temperature, and salinity, we can assume d_b to be one gram per cubic centimeter and thus convert the difference in density immediately to extra brine content because of air. Thus, from Figure 5 a temperature of −7°C and salinity of 5‰ gives a brine content by volume of 4 pct. Adding to this 0.5 pct for the air gives us a β for computation purposes of 4.5 pct by volume.

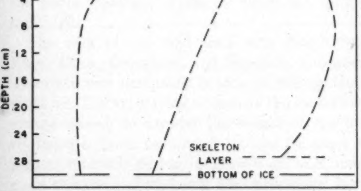

FIG. 9 – Typical salinity, temperature, and strength profiles through a sea-ice sheet

Conclusions—Because of the complexity of sea ice the derived formulas and curves are necessarily very general, but they give a first and, we believe, an accurate picture of the relation between strength and the major controlling factors.

The following considerations enter into a more detailed analysis of sea-ice strength:

(1) Surface tension probably has an appreciable effect on the cohesion of the ice plates.

(2) Sometimes the brine pockets do not entirely pierce the section under consideration vertically. This will not materially change the argument for tension, since for a given β_e the effective cross-sectional area will be the same, regardless of distribution of the brine. However, as can be seen from the flexural strength formula, the distribution of the brine materially affects the results of flexural calculations. If the brine pockets do not entirely pierce the section then the effective thickness, as well as the effective width, will be changed.

(3) The argument is developed for thin sheets in which the temperature and salinity are constant throughout. A thicker sheet is made up of many layers, each with its own temperature, salinity, and strength. A complete analysis of the strength of thick ice must include a variation of the constants throughout the section. A variable cross section should be used in calculation. Figure 9 gives a typical temperature and salinity profile through the sheet, and a strength profile using results from Figure 7.

(4) The geometry of the brine pockets, especially along breaks, must be studied further. The constants a, $2r$, and k can be changed, if necessary, as a result of further measurement, and perhaps the factors controlling the magnitude of these constants can be determined.

(5) The assumption of a constant k may fall down at high brine content when all the brine pockets are large, and at very low brine content. The theoretical strength at high temperature and salinity may be too low. The theory is general enough to include changes in stress concentration.

(6) The effects of plasticity and recrystallization have not been considered.

(7) Only breaks parallel to the small plates have been considered. Certain small-scale strength tests cause the ice to artificially break across the plates. Other tests load the ice parallel to the optic axis or to other directions which do not occur in an in-place ice sheet. Also, shear, torsion, impact, and compression tests are commonly performed. These tests can also be considered theoretically. Tensile,

or flexural, strength is usually the only strength property that is important in calculating the bearing strength of an ice sheet. The tensile strength of the warm underside of the ice is the most important single quantity.

(8) Inter-plate slippage may prove to be an important factor, especially in slowly applied loads.

(9) The quantitative effect of solid salts on very cold ice has not been considered in the present analysis. Work is continuing on this problem.

(10) 'Pure' lake ice itself has many stress concentrators, mostly minute air bubbles. If it is determined that these stress concentrations actually affect the strength by a factor of three, the numerical results reported in this paper are low. The formulas developed are still valid until solid salts precipitate in quantity but a higher value of σ_p must be used in numerical computations. σ_p refers to absolutely pure ice and has probably never been measured except possibly on very small samples. The ability of warm ice and ice next to the liquid phase to maintain a stress concentration must be studied. If the ice is not perfectly elastic, we would expect the stress concentration to be low in warm ice and to approach three in colder ice.

Acknowledgments—Field observations used in this study were made as part of the Sea Ice Bearing Strength Project, a joint effort of the Air Force Cambridge Research Center, the Snow, Ice, and Permafrost Research Establishment (SIPRE), and the Navy Hydrographic Office. We wish to thank A. Assur and T. R. Butkovich for their advice on many of the problems associated with this study. A. Assur and E. Little kindly read the manuscript and offered many helpful suggestions. L. Hansen of SIPRE allowed the authors to use the unpublished results of his in-place cantilever beam tests. John Grady and Eugene Whitney provided invaluable assistance during the period of testing at Thule, Greenland. Photographs are by W. F. Weeks.

An Experimental Study of Strength of Young Sea Ice

WILFORD F. WEEKS AND DON L. ANDERSON

***Abstract*—Values for the strength of sea ice are extremely sparse in the literature, and available values show a wide, unexplained variation. Results of in-place cantilever beam tests presented in this paper show a definite relationship between flexural strength and brine content. Values for Young's modulus are also experimentally determined. It is shown that the bearing capacity of a sea-ice sheet is dependent on the brine content and that thin ice sheets are capable of supporting a large 'super load' beyond the force necessary to form the first crack.**

Introduction—Detailed studies of the basic physical properties of sea ice are very few. *Malmgren's* [1927] work still remains the standard reference. In particular, information regarding the strength characteristics of sea ice is noticeably absent. Inasmuch as increased activity in the polar regions during IGY has necessitated the use of unprepared sea-ice surfaces as floating platforms for scientific activity, the bearing strength of sea ice has become an extremely critical problem.

The specific objectives of the present study are: (1) to determine the relations between the flexural strength and Young's modulus of sea ice and such parameters as ice temperature, salinity, and density; (2) to calculate the bearing capacity of young sea ice; and (3) to develop theoretical relations for the analysis of sea-ice strength based on the observed distribution of brine and air pockets so that it will be possible to extend experimentally determined strength curves.

The present study considers only in-place cantilever tests on thin (<40 cm), newly formed sea ice. This material was chosen since there is a large variation in its brine content and it is thin enough so that a large number of strength tests could be performed in a reasonable amount of time. This was considered necessary since previous work by *Petrov* [1955] has shown that the results of small sample strength tests on sea ice show a large scatter. Also, these tests duplicate conditions on the warm underside of the ice where the ice initially fails.

The sites of the field tests were North Star Bugt, Thule, Greenland, and Hopedale, Labrador. The tests were performed in areas of homogeneous sheet ice. Testing started as soon as the ice became strong enough to support the weight of the test equipment. Tests were made on this ice sheet at regular intervals during its growth up to a maximum thickness of 40.2 cm. This procedure, however, made it possible to collect only a very small amount of information during the freeze-up period since at any given ice thickness the ice can be tested at only one temperature and salinity. To avoid this difficulty, a number of large ponds (rectangular ice-free areas) were cut in the ice. These ponds were allowed to freeze on different dates so that ice of varying thickness and salt content could be tested during a period of a given air temperature.

The majority of published sea-ice strength tests have been made using small samples that were removed from the ice sheet and allowed to reach equilibrium with the air temperature [*Butkovich*, 1956; *Petrov*, 1955; *Veinberg*, 1940]. This type of testing is not suitable for studying very young sea ice, because when the specimen is removed from the water (1) a large portion of its brine content is lost by drainage; (2) it is often not capable of supporting its own weight; and (3) it is impossible to re-establish the exact in-situ temperature gradient. Also, the results of in-place, cantilever tests show a much smaller scatter than most small-sample tests [*Butkovich*, 1956]. Therefore all the tests were performed in place in the ice sheet so that the physical properties of the specimen would be identical to those of the over-all sheet.

Flexural strength—The general technique for obtaining the in-place flexural strength of sea ice was used by *Neronov* [1946] and other Russians, earlier, to measure the flexural strength of lake ice. First a U-shaped channel is cut in the ice sheet with an ice-pond saw. This channel isolates an in-place cantilever ice beam with one end attached to the sheet. Both pull-up and push-down tests were performed on these beams. On the pull-up tests a chain is placed around the end of the ice beam and attached to the end of a wooden lever. A force is then applied by rolling a heavy barrel from the fulcrum to the end of the lever. From the weights and positions of the chains, lever, and barrel at the time the ice beam breaks, the force applied to the end of the in-place beam can readily be computed. When the ice was very thin, the force was applied manually, using a dynamometer to measure the force at the end of the ice beam.

The push-down tests were performed using an additional lever that was anchored to the ice sheet. This lever transmitted a downward force to the end of the ice beam. When push-down tests were made on thin ice, a known weight attached to a dynamometer was lowered manually onto the end of the ice beam. In this case the force at the time of failure is simply the known weight minus the dynamometer reading.

The cantilever beam width was kept roughly ½ to 2 times the ice thickness and the length between 3 and 6 times the ice thickness. The average loading rate during the tests was 0.5 kg/cm^2 sec.

After failure the broken segment of the ice beam was immediately removed from the water and three measurements each were made of its length and its height and width at the failure cross section. Three measurements were necessary because of the irregularity of the break. A 7.6-cm diameter vertical core was taken from the sheet in the area of the tests, for the determination of a salinity profile. The ice samples from the core were immediately

[a] These tests were performed by Lyle Hansen of SIPRE.

placed in tightly sealed glass containers and allowed to melt. The density of the resulting solution was measured, using hydrometer floats from a salinity kit manufactured by G. M. Manufacturing Co., New York 12, N. Y. All values were corrected to 15°C, using a table supplied by the manufacturer. The temperature of the beam was measured at two or three levels using Weston dial thermometers inserted into drilled holes. The average temperature of the ice sheet was then determined by using both the results of the dial thermometer measurements and temperatures measured by a series of thermocouples frozen into the ice sheet at 10-cm vertical intervals. Typical temperature and salinity profiles during the period of testing are shown by *Anderson* and *Weeks* [1958, Fig 8].

The flexural strength is computed from

$$\sigma = 6PL/wh^2 \tag{1}$$

where P is the force applied to the end of the ice beam at failure; L the distance from the point of application of the force to the point of breakage; w the average width of the ice beam, and h the average thickness of the ice sheet. The results of these tests are presented in Table 1, and σ is plotted against average ice salinity and ice temperature in Figure 1. Each point is the average of all the tests on a given sheet. The push-down tests are identified in the legend. The remainder are pull-ups.

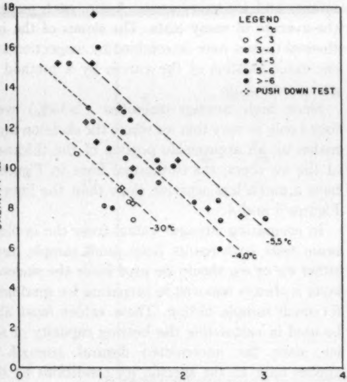

FIG. 1 – Plot of experimental values for flexural strength of sea ice versus salinity at various temperatures, not allowing for the skeleton layer

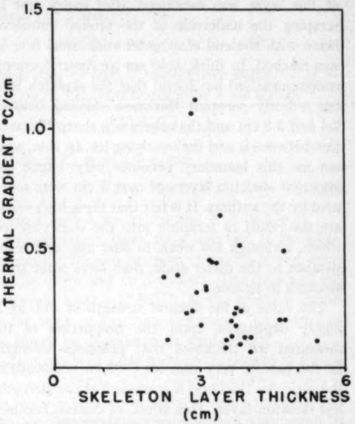

FIG. 2 – Plot of skeleton-layer thickness versus thermal gradient across the ice sheet

The above formula must be considered as only approximate as applied to sea ice. First, the properties of sea ice vary considerably with depth. A variable section modulus should be used in more accurate work. Secondly, the stress concentration at the butt end of the cantilever has been neglected. This permits our work to be compared directly with that of previous investigators.

The study was undertaken to identify the controlling factors in sea-ice properties and thus relative strengths are studied.

It is surprising that the pull-ups and push-downs give essentially the same results. The strength of the beam is determined primarily by the strength of the extreme fiber that is in tension. In push-downs this is the cold upper part of the sheet; for pull-ups it is the warm, weak underside. However, we show [*Anderson* and *Weeks*, 1958] that the bottom and top are the weaker parts of the ice and the maximum strength exists somewhat above the center of the sheet. The low strength of the top is due to the extremely high salinity which only persists to a very small depth.

At the lower surface of the growing ice sheet there is a strengthless layer of unconnected vertical ice plates which has been referred to by Assur as the skeleton layer [*Butkovich*, 1956]. The thickness of this layer was measured after every test by scraping the underside of the broken cantilever beam with the end of a meter stick until firm ice was reached. In thick, cold sea ice Assur (personal communication) has found that the skeleton layer has a fairly constant thickness varying between 2.4 and 2.8 cm and that there is a sharp demarcation between it and the overlying ice. In thin, weak sea ice this boundary becomes very vague and apparent skeleton layers of over 5 cm were measured by the authors. It is felt that these high values are the result of scraping into the overlying ice, which, although too weak to offer appreciable resistance to the meter stick, does have some small strength in tension.

The value of the flexural strength of thin ice is highly dependent upon the proportion of the measured ice thickness that possesses strength. In the case of very thin ice (<3 cm), essentially the entire ice thickness is composed of the strengthless skeleton layer. This effect, of course, becomes lessened as the ice sheet grows since the skeleton layer remains roughly constant. A number of attempts have been made to relate apparent variations in the skeleton layer to other properties. Figure 2 shows skeleton layer thickness plotted against the thermal gradient in the ice sheet. At the present, however, no definite empirical relation has been established. A theoretical relation has been derived [*Anderson* and *Weeks*, 1958].

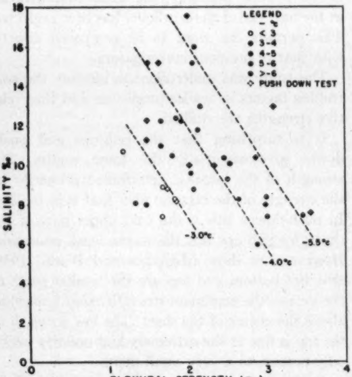

FIG. 3 – Plot of experimental values for flexural strength, assuming a constant 2.8-cm skeleton layer

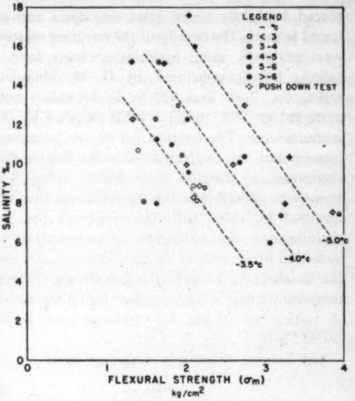

FIG. 4 – Plot of experimental values for flexural strength, using the measured skeleton layer

Therefore two other strength values were calculated: σ_K using for h in (1) the measured ice thickness minus 2.8 cm (assuming a constant value for the skeleton layer) and σ_M using the measured ice thickness minus the measured value of the skeleton layer. Figures 3 and 4 show the flexural strengths, σ_K and σ_M, plotted against average ice salinity and ice temperature. Again, each point is the average of many tests. The slopes of the isothermal curves were determined by inspection and the exact location of the curves by a method of group averaging.

Since high average salinities (>14‰) were found only in very thin ice where the skeleton layer makes up an appreciable portion of the thickness of the ice sheet, the isothermal lines in Figure 1 have a much less negative slope than the lines in Figures 3 and 4.

In comparing strength values from the in-place beam tests with results from small sample tests, either σ_K or σ_M should be used since the skeleton layer is always removed in preparing ice specimens for small sample testing. These values must also be used in calculating the bearing capacity of sea ice, since the uncorrected flexural strength σ applies only to the specific ice conditions at the time of testing, that is, portion of the ice sheet that is skeleton layer.

Young's modulus—For the measurement of Young's modulus on in-place samples of young sea ice, a semi-infinite beam test developed by A. Assur of SIPRE was used. The test procedure is as follows: a 30-cm × 16-m semi-infinite ice beam is cut in the ice sheet. A force is then applied to the free end of the beam causing the beam to break at a distance L from the position of the applied force. The process is then repeated at the new end of the beam. After a number of segments are broken off, the average length of each segment, the thickness of the ice and skeleton layer, and its salinity and temperature profiles are measured.

It can be shown [*Hetényi*, 1946] that for a semi-infinite beam on an elastic foundation

$$M = -(P/\lambda)\, e^{-\lambda l} \sin \lambda l \qquad (2)$$

where M is the bending moment, P the vertical force applied to the end of the beam, l any distance from the end of the beam, and λ the characteristic of the system defined as

$$\lambda = \sqrt[4]{wK/4EI} \qquad (3)$$

where w is the width of the beam, K the foundation modulus (in this case equal to the density of sea water of $\sim 32‰$ salinity at its freezing point, which is $\sim$ 1.0 g/cm³); E is Young's modulus (the Young's modulus determined by this test is definitely not a reversible process where the sample returns to its initial dimension after testing); and I is the moment of inertia $wh^3/12$, where h is the thickness of the beam. This is only approximate since the beam is not homogeneous throughout its thickness. This semi-infinite beam will break at the position where the bending moment M is at a maximum. Therefore

$$dM/dl = -Pe^{-\lambda l} (\cos \lambda l - \sin \lambda l) \qquad (4)$$

which goes to zero at consecutive values of $\lambda l = \pi/4, 5\pi/4$, etc. Substituting for λ we obtain

$$\sqrt[4]{3K/E h^3} = \pi/4l \qquad (5)$$

But since $K = \cong 1.0$ g/cm³

$$E = 7.88\, L^4/h^3 \qquad (6)$$

where L and h are in cm and E is in g/cm².

In performing these tests care had to be taken to prevent friction between the sides of the semi-infinite beam and the ice sheet. The length of the beam was kept $>(1.5\pi)/\lambda$. If the effective length of the beam is less than this value, the beam can no longer be considered as semi-infinite.

The results of these tests are presented in Figure 5. A large scatter in the values is evident. There is no obvious relation between Young's modulus and the ice temperature and salinity. This result is rather surprising since other properties of sea ice are definitely a function of the brine content. The lack of a relation between these properties is obviously caused by the large scatter in the experimental values and insufficient data. Owing to the nature of the test procedure, it is difficult to determine the values of E_K or E_M (the subscripts have the same meaning as in the preceding section) with accuracy, since Young's modulus is inversely proportional to the cube of the effective thickness

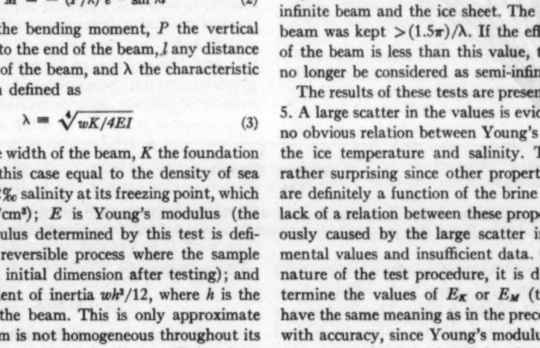

FIG. 5 – Plot of Young's modulus as determined from semi-infinite beam tests

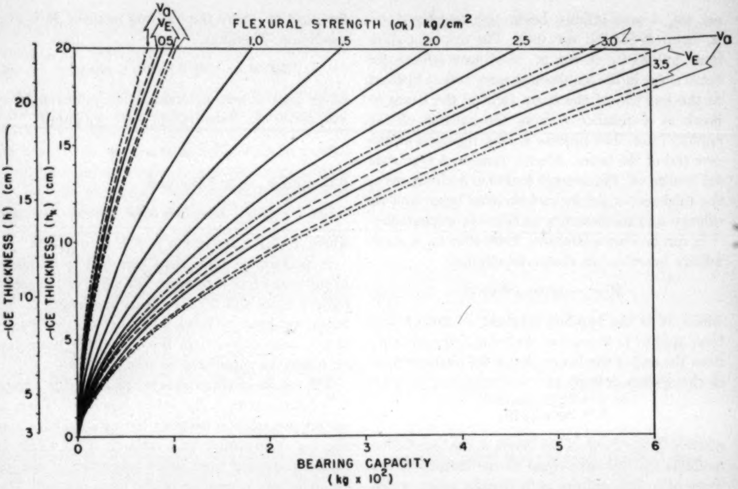

FIG. 6 – Curves showing relationship between bearing strength of a sea-ice sheet and thickness at various values of flexural strength and showing the effect of changing the load radius and changing Young's modulus

of the ice sheet, the value of which, as discussed earlier, depends on an exact measurement of the thickness of the skeleton layer. There is however general agreement between the values for E_K and E_M which average 3570 and 3800 kg/cm² and values determined graphically from the slopes of small sample stress-strain curves by *Butkovich* [1956] on much colder ice. His values varied from 4520 to 10,225 kg/cm² in the temperature range of −4.9 to −18° C.

Bearing capacity—It is interesting to use the experimentally determined values of σ_K and E_K to calculate the ice thickness required to support a walking man and other light loads. This can be done using an analysis developed by *Hertz* [1884] and *Wyman* [1950]. Considering the sheet of thin ice as an infinite isotropic elastic plate resting on an elastic foundation, the force P necessary to cause the first crack is given by

$$P = \frac{\pi \sigma_K b h^2}{3(l + \gamma) kei'b} \tag{7}$$

where γ is Poisson's ratio, $kei'b = (0.6159 - \ln b)(b/2) + \pi b^3/64 + \cdots$ [*McLachlan*, 1941] and $b = a/l_1$ where a is the radius of the circular loading and l_1 is the so-called radius of relative stiffness defined by

$$l_1 = \sqrt[4]{D/K} \tag{8}$$

where K is the foundation modulus and D the flexural rigidity

$$D = E_K h^3/12(1 - \gamma^2) \tag{9}$$

Figure 6 shows the bearing capacity at the first crack plotted against the measured ice thickness h, the effective ice thickness h_K, and the flexural strength σ_K. The values used in calculating these curves are E_K = 3570 kg/cm², a = 15 cm, γ = 0.36, and $K = 10^{-3}$ kg/cm³. The change in the position of the σ_K = 0.5 and 3.5 kg/cm² curves are shown for the values of E_K = 1000 and 8000 kg/cm² (the maximum variation in the measured values) and a = 7.5 and 22.5 cm. As can be seen there is less variation (V_E) in the bearing capacity from a reasonable change in magnitude of E_K than from a reasonable change V_a in a. Therefore even though the Young's modulus tests discussed earlier in this paper did not give a precise determination of E_K, the measured values can be used to calculate the bearing capacity of an ice sheet without introducing an appreciable error.

It is interesting to compare the calculated bearing strengths with observations made during the Thule freeze-up. One of the authors (DLA) was trapped on the off-shore side of a newly frozen lead of a width of ~15 m. As he crossed the lead, using a rapid shuffle, an extreme deflection was noted in the ice sheet and a series of large waves was observed in the ice. When he paused to study the deflection dish around him, a soft crackling sound and a rapid sagging were noted. The ice in the center of the lead was 8 cm thick. Two days later the authors repeatedly crossed over ice areas of 10 cm in thickness, and, although a noticeable deflection was observed, there was no evidence of breakthrough even after jumping on the ice. The weights of the persons in these instances was ~90 kg and σ_K was estimated to be ≤ 1.5 kg/cm^2. From Figure 6 it can be seen that when the ice thickness was 8 cm the ice was loaded far beyond the first crack. Upon stopping, the man probably would have broken through the ice in a short period of time. With 10 cm of ice, however, even though the ice sheet was loaded slightly beyond the first crack, it was able to support the load for an appreciable length of time without noticeable signs of failure. This conclusion is in agreement with studies of A. Assur (personal communication), who has shown by comparing field tests with theoretical computations that ice sheets are capable of supporting a large 'super load' beyond the force necessary to form the first crack.

The Effects of Entrapped Gases on the Hydraulic Characteristics of Porous Media

GERALD T. ORLOB AND G. N. RADHAKRISHNA

Abstract—Investigation of the hydraulic characteristics of prepared porous media indicate that a ten per cent increase in air content of media voids is capable of producing a 15 pct reduction in 'effective porosity,' a 35 pct decrease in permeability, and about 50 pct reduction in hydraulic dispersion. The location of bubbles in large or small pores affects the uniformity of pore sizes and determines the amount of water saturated void volume which is isolated by air bubbles. The shape of the chloride tracer 'breakthrough' curve is greatly modified by changes in uniformity of pore size. An appreciation of the effects of gas accumulation is essential to a proper interpretation of the hydraulic behavior of natural formations.

A thorough engineering appraisal of the hydraulic characteristics of a particular porous medium is essential to an intelligent interpretation of the probable performance of this material in the transmission of ground water in situ. In particular, the ground-water geologist or engineer should determine the porosity and permeability for the medium under conditions which are likely to be obtained in practice. He should also be aware of the variable nature of the hydraulic characteristics of the medium as a consequence of changes in climatic or geologic conditions or variations in water quality.

Many factors govern the hydraulic properties of natural aquifer materials. The physical characteristics of the water are particularly important and their effects are well understood. The characteristics of the medium; its particle size, shape, and distribution, its chemical composition; and the geologic structure of the aquifer in which it is deposited are likewise important and generally appreciated by both engineers and geologists. If, however, in addition to solid and liquid phases, a gaseous phase is present in the system an interpretation of the hydraulic behavior of the medium is somewhat complicated. Often the gaseous phase may be justifiably ignored with no appreciable error in result. But, occasionally the influence of accumulated gases may be great, as for example, in the case of artificial ground-water recharge; and cannot be neglected.

It is the particular objective of this paper to explore the problem of gas accumulation in porous media and to illustrate by the presentation of experimental results the effects of this phenomenon on the hydraulic characteristics of the medium. Particular attention is given to media porosity and permeability and hydraulic dispersion of transmitted water.

Sources of entrapped gases—Some of the more significant influences on the hydraulic performance of a porous medium are those occasioned by the entrapment of gases in interstitial cavities. Such gas accumulations may originate by liberation of any or all of the components of the atmosphere which were originally dissolved in and in equilibrium with natural ground-water recharge. Temperature increases during underground percolation with the resultant reduction in equilibrium saturation can bring about the evolution of dissolved gas. Similarly, pressure differences, especially tensions developed in the capillary fringe near the ground-water table or vertical percolation of water through strata of varying permeability can cause the evolution of dissolved gases.

The products of decomposition of organic sedimentary deposits commonly include such gases as carbon dioxide, methane, and hydrogen sulfide. Evolution of these gases and their eventual migration or displacement into water-transmitting aquifers can also lead to significant gas accumulations in media voids.

Natural-gas deposits which may be displaced by flooding operations or which may be intercepted by natural faulting or by drilling operations can contribute to gas accumulation in adjacent water-bearing strata.

Currently, attention has been directed to methods of artificial ground water recharge such as direct injection [*McGauhey* and *Krone*, 1954] and surface spreading [*Greenberg*, 1953; *Orlob* and *Butler*, 1955]. Waste waters which have been considered for reclamation range from excess surface runoff or irrigation water to diluted domestic sewage. Dissolved organic solids and the bacteria which are required for stabilization may thus be introduced into producing aquifers. Subsequent breakdown of organic matter can result in production of carbon dioxide or other gases of decomposition in excess of the ability of the aquifer to remove them.

Movement of the gaseous phase—The ultimate persistence of accumulated gases in a given location may depend on the capacity of the liquid phase for solution of the gas and the hydraulic forces which develop behind an individual bubble and tend to move it forward through the medium.

If gas is continually supplied through the liquid phase in excess of saturation, an equilibrium between liquid and gas is established and the gas accumulation may remain constant. According to *Wyckoff* and *Botset* [1936] the gaseous phase remains static, that is, the medium is impermeable to the flow of gas, until a so-called 'equilibrium saturation' is attained. In studies by these investigators on four different sands (permeability range 17.8 to 262 Darcy's) the equilibrium saturation was noted to correspond to about 11 to 27 pct gas in the media voids and was found to be roughly proportional to the permeability. Permeabilities associated with equilibrium saturation were termed 'equilibrium permeabilities.'

[a] Per cent by weight.

The Wyckoff and Botset investigations were concerned primarily with high gas-to-liquid ratios such as might result during flooding operations for gas recovery in an oil field. Contrariwise, the problem of greatest concern to the geohydrologist it that of low gas-to-liquid ratios, particularly those in which the gaseous phase is static. The investigations discussed in this paper deal with the latter problem, that of gas accumulations in the range of 0 to 25 pct of the total void volume.

Experimental procedure—The program of investigation was designed to illustrate as simply as practicable the effect of gas accumulation on (1) the effective porosity of the medium, (2) the permeability of the medium to water, and (3) the hydraulic dispersion of water passing through the system. Apparatus for the studies was simple in design, consisting of a cylindrical glass column about one meter in length and about 32 mm in diameter fitted with an underdrain of fine screen, a discharge tube of variable diameter, an overflow for the regulation of hydraulic gradient, and supply reservoirs. The media column was so designed that when in operation the fluid pressure was nearly uniform along the axis of the column, equivalent to about two inches of water. The physical arrangement of equipment is shown in Figure 1.

The media used in the experiments were obtained by sieving, from the same parent stock, fractions which were as uniform as possible and very nearly of geometrically normal size distribution. Individual grains were slightly rounded with a maximum length to width ratio of about 1.5:1.0 and were composed largely of quartz and feldspars. In order to study the effect of non-uniformity of size on the hydraulic characteristics of the media several samples were prepared by mixing fractions of uniform materials to obtain the desired size distribution. A few investigations were carried out on a disturbed sample of a highly permeable agricultural soil; Oakley sand. Table 1 summarizes the characteristics of the various materials employed in the experiments.

Columns were packed by pouring the media into the column at a constant rate while the assembly was continuously vibrated. Care was taken to minimize stratification or sorting of individual grains during packing. When the columns were assembled the absolute porosity was determined by gravimetric methods using column volume, media weight, and a specific gravity of 2.69. Subsequently, columns were subject to a vacuum of approximately 30 inches of mercury and saturated from the top down with freshly distilled water. The entire saturated assembly was carefully weighed on a beam balance.

In order to produce variation in air content in the media voids, the columns were periodically drained and refilled in such a manner as to entrap air bubbles deliberately. The volume of air so entrapped was determined by weight difference in subsequent weighings of the assembly. Since it was not possible to weigh the assembly when in actual operation it was expected that small errors would result from variations in pressure in the gaseous phase. However, the magnitude of the maximum possible error from such causes was estimated to be less than the errors of observation. In general, the results reported herein were reproducible within a standard deviation of about two percent.

Permeabilities for the various experimental conditions were determined by an application of Darcy's law

$$K = Q/As \tag{1}$$

Where K is the coefficient of permeability, Q is the discharge through a cross sectional area A, and s is the hydraulic gradient imposed on the system.

A dimensional consideration of Darcy's law relates K to the properties of the fluid and solid phases through the equation

$$K = \text{Const.}\, d^2/\nu \tag{2}$$

Where d is a characteristic dimension of the medium, often taken as an effective grain size, and ν is the kinematic viscosity of the fluid. The numerator is usually designated as simply permeability k in darcys and is a function only of the solid phase of the porous media system. While Wyckoff and Botset asserted that Darcy's law is inadequate to describe the dynamic behavior of non-homogeneous fluid mixtures it has been well established in previous studies on porous media, by *Day* and *Luthin* [1953] and *Orlob* and *Butler* [1956], that the fundamental relation is applicable to water movement as long as the liquid phase remains continuous through the medium. Columns of uniform porous media have been successfully operated with as little as 25 pct of the void space occupied by water which flowed over grain surfaces as a laminar film [*Orlob* and *Krone*, 1956].

In order to apply Darcy's law to the problem of estimating velocity of water movement through a liquid – gas – solid system it is essential to evaluate the so-called effective porosity of the medium, the fraction of the absolute void volume which actually transmits water. Effective porosity f_e is defined as

$$f_e = \frac{V_e}{V_t} = \frac{V_v - V_a - V_b}{V_t} \tag{3}$$

Where V_t is the bulk-media volume including voids, V_e is the volume of readily displaceable pore water, V_v is the absolute volume of voids, V_a is the volume of air entrapped in the voids, and V_b represents the volume of stagnant pore water which is isolated in the medium from the dynamic liquid phase. Chemically bound water, which was considered negligible in the media employed in these studies, can normally be included in the term V_b.

Effective porosity can be independently evaluated for a given medium with the aid of a water tracer [*Kaufman* and *Orlob*, 1956]. If a water tagged with a tracer which does not enter into chemical reactions with the liquid or solid phases, is passed through a porous medium a characteristic breakthrough curve results at a downstream sampling point. The concentration of tracer gradually increases from zero to the full initial concentration over some time (or distance or volume displacement) which is characteristic of the physical and hydraulic properties of the particular media. All breakthrough curves reported in this paper were obtained using chloride ion as a tracer. Previous experience has shown that chloride when used in low concentrations possesses most of the attributes of the ideal water tracer. A typical tracer curve is shown in Figure 2.

If the tracer curve is normalized so that the ordinate is expressed as a ratio of sample concentration to initial concentration and the abscissa is given as a ratio of volume displaced to total media volume then the effective porosity is represented by the area over the curve as

$$f_e = \int_0^\infty \left(1 - \frac{C}{C_0}\right) d\left(\frac{V}{V_t}\right) \tag{4}$$

Thus the tracer curve serves as a means of estimating the fraction of the pore volume which participates actively in the flow.

In a medium which does not react chemically or biologically with the tracer the shape of the tracer curve is dictated only by the geometry of the passages which transmit the liquid carrying the tracer. If statistical isotropy is obtained in the assemblage of media pores, the dispersion of the tracer front as it progresses through the medium is brought about by a disordered series of movements superimposed on the basic flow regime. Such a pattern as would theoretically result from a statistical treatment by the random-walk technique or a solution of Fick's second law of diffusion [*Rifai*, 1956] is conveniently described by the equation

$$\frac{C}{C_0} = \tfrac{1}{2}\left[1 - \operatorname{erf}\frac{L - \bar{v}t}{2\sqrt{Dt}}\right] \tag{5}$$

Where L is the distance between the point of tracer entrance and the sampling point, $\bar{v}$ is the average velocity of water movement through the media pores, and t represents the time of travel of a particular element of fluid to the sampling point. The coefficient of dispersion D defines the shape of the tracer curve on a dimensionless plot of C/C_0 against t/t_0 where t_o is taken as the time for $C/C_0 = 0.5$ to arrive at the sampling point.

It was observed by *Rifai* [1956] and also *Orlob* and *Krone* [1956] that the coefficient of dispersion was directly proportional to the velocity of flow

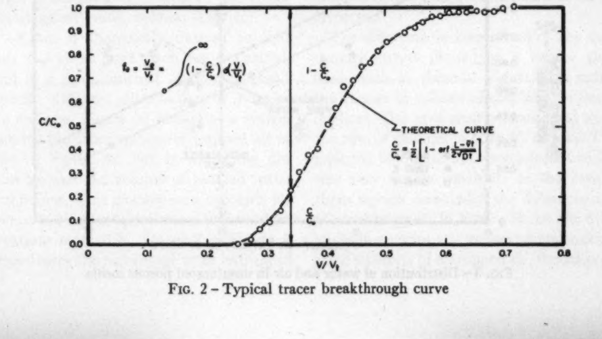

FIG. 2 – Typical tracer breakthrough curve

$\bar{v}$. The latter investigators pointed out, however, that dispersion, *per se*, is independent of velocity and that the ratio of D to $\bar{v}$ is a constant for a given porous medium system. *Orcutt* and coworkers [1957], letting $D\bar{v} = D_m$, the socalled medium dispersion constant, have rewritten (5) in the form

$$\frac{C}{C_0} = \frac{1}{2}\left[1 - \operatorname{erf}\frac{1 - \dfrac{V}{V_e}}{2\sqrt{\left(\dfrac{D_m}{L}\right)\left(\dfrac{V}{V_e}\right)}}\right] \tag{6}$$

Where V/V_e is the ratio of the volume of water displaced to the hydraulically effective void volume, L is the distance of flow, and D_m is a constant which characterizes the hydraulic dispersion properties of the medium.

Effective porosity and air accumulation—A comparison of the absolute void volume of a porous medium V_v with the displaceable water volume V_e for a known amount of air entrapped V_a permits an estimation of the amount of water in the system which does not participate in the flow V_b. When the medium is completely saturated the value of V_b should be minimal; it was, in fact, observed to be virtually zero for the various materials used in these studies. For example, the effective porosity for saturated sand E was estimated from the area ahead of the chloride breakthrough curve to be 0.401. A determination based on gravimetric techniques using a specific gravity of 2.69 (determined by water displacement at 20°C) gave an absolute porosity of 0.402. The close agreement between these two techniques is satisfactory evidence that the column was completely saturated and that a negligible amount of stagnant water was contained in the system, that is, $V_e = V_v$ when the medium was saturated.

Entrapment of a small amount of air in the pore spaces of the medium produced a volume discrepancy which could only be accounted for by assuming that some of the water contained in the voids was actually trapped by the air bubbles in such a way that it was isolated from the main stream of flow and was not displaced during the passage of the chloride tracer. As might be expected the volume of water so isolated varied considerably with each individual set up, ranging up to about 5 pct and averaging about 2.5 pct of the total pore volume.

A comparison of displaced volume to the void volume for all of the tests which were conducted with sufficient detail to permit calculation of the required quantities is shown in Figure 3. It is to be noted that no discernible trend in V_b with per cent air entrapment is apparent and that all values fall below the line $V_e/V_v = 1 - V_a/V_v$.

The manner in which a portion of the void volume isolated from the main flow regime is illustrated schematically in Figure 4. A typical section taken parallel to the axis of flow in a column of heterogeneous sand can be expected to appear somewhat as shown in Figure 4a. Pores of varying size are distributed through the medium in a somewhat random manner and occasional pockets of small grains may exist.

When air is admitted to the larger, more easily drained pore spaces, small bubbles are formed

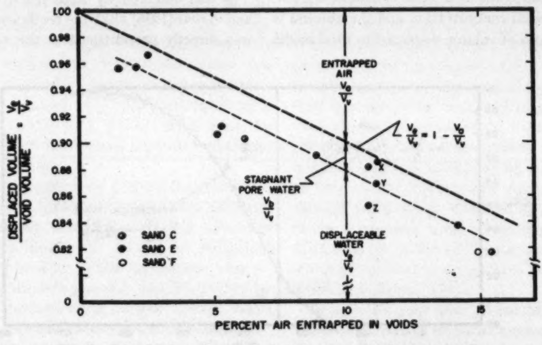

Fig. 3 – Distribution of water and air in unsaturated porous media

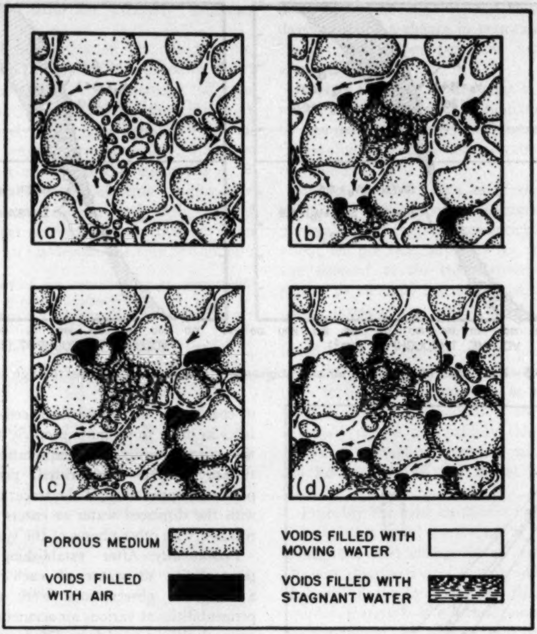

(a)
(b)
(c)
(d)
POROUS MEDIUM
VOIDS FILLED WITH AIR
VOIDS FILLED WITH MOVING WATER
VOIDS FILLED WITH STAGNANT WATER

Fig. 4 – Distribution of air and water in a porous medium; (a) voids saturated with water; (b) five per cent air in voids; (c) ten per cent air in voids (large voids only); (d) ten per cent air in voids (all void sizes affected)

Upon resumption of flow (Fig. 4b) these bubbles are forced into the small crevices leading out of the pore spaces thus sealing off a portion of the water filled medium from active participation in the flow. Further increases in air volume entrapped in the larger pores produce comparatively minor changes in stagnant water volume (Fig. 4c).

If the column is thoroughly drained so that small pores as well as large pores are evacuated, entrapment of a given amount of air may result in an entirely different distribution of bubbles within the medium. Figure 4d illustrates a system which contains the same volume of trapped air as that shown in Figure 4c, but in which the distribution of air and the volume of isolated water are quite different. This phenomenon accounts for the difference in stagnant pore water indicated for the observations marked X, Y, and Z in Figure 3. In these three cases the percentage of air entrapped ranged only between 10.9 and 11.2 pct while the stagnant water was estimated to vary from 0.5 to 4.0 pct of the total pore volume. As will be demonstrated later these differences produce a negligible change in the permeability of the medium but have considerable influence on hydraulic dispersion.

The difference in area ahead of any two breakthrough curves plotted on a volume throughput basis, such as those in Figure 5, is indicative of the change in volume of displaceable liquid in the medium. This area must be considered as reflecting the sum of changes in both V_a and V_b. The curves reported in Figure 5a, were selected such that V_b was very nearly constant; so the area between them reports essentially the difference in volume of air entrapped. In Figure 5b, on the other hand, while the curves still represent approximately the same amounts of entrapped air, the stagnant-water

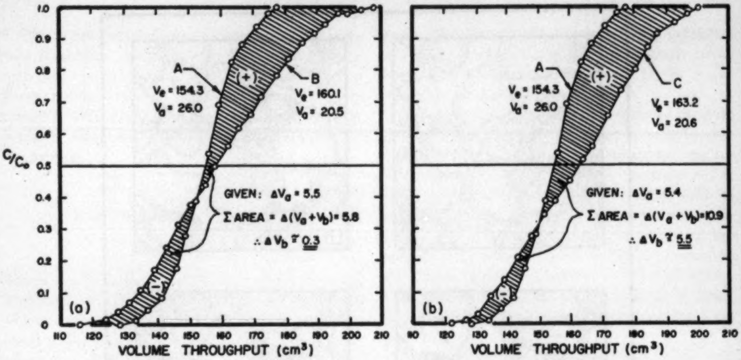

FIG. 5 – Estimation of entrapped air and stagnant water from chloride breakthrough curves

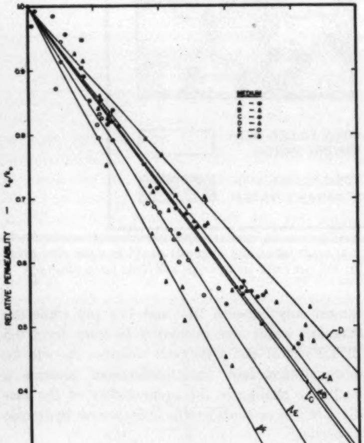

FIG. 6 – The effect of air entrapment on the permeability of porous media

volume is no longer equal in the two cases. The area between the curves in this latter case represents the sum of differences in air and stagnant water.

It is apparent that if tracer curves are to be used in water-flooding operations in an oil field, for example, care must be exercised in interpretation of changes in shape and displacement characteristics in order to estimate properly the changes in the porous medium. Interpretation is unquestionably further complicated, perhaps to the point of impossibility, if the tracer does not move with the displaced water or enters into chemical reaction with other phases of the system.

Permeability—After establishing the initial permeability to water of each test medium a series of observations were made of the permeabilities at various air accumulations. Initial permeabilities ranged from 478 darcys for medium A to 8.7 darcys for medium F. Air was accumulated in the various media in volumes sufficient to reduce the permeability to less than one-half of the original value. The results of these tests are summarized graphically in Figure 6.

In each of the six cases reported, the relationship between permeability and air accumulation was essentially linear, taking the general form

$$k_a/k_0 = 1 - m(V_a/V_v) \qquad (7)$$

in which V_a/V_v is the fraction of the original void volume occupied by air, k_a/k_0 is the ratio of the permeability of a partially saturated medium to the permeability of the same medium fully saturated, and C is a coefficient.

The extreme sensitivity of permeability to gas accumulation in the pore spaces of porous media is readily apparent upon inspection of the data in Figure 6. The values of m taken from the graphical lines of best fit were found to range from 0.23 to 0.39, that is, a ten per cent air accumulation caused a permeability reduction generally exceeding 23 pct.

There is a strong indication from the data presented for media D, E, and F that the permeability change increases with non-uniformity of grain sizes. Uniformity coefficients for these materials were, respectively, 2.28, 3.06, and 3.88 while the corresponding values of *m* were 0.23, 0.33, and 0.39. The most uniform media, specimens A, B, and C with uniformity coeficients ranging from 1.28 to 1.60, showed comparatively little variation in the coefficient *m*. A cursory examination of the characteristics of Oakley sand, a very non-uniform material with an initial permeability of about 1.6 darcys showed a change in permeability of about 39 pct for a ten per cent increase in air accumulation.

A minor tendency for the value of *m* to decrease with an increase in size of medium is also suggested by the data but insufficient information was obtained for conclusive interpretation of such a relationship.

Inspection of the data of *Wyckoff* and *Botset* [1936], although it does not document adequately permeability changes for gas accumulations below about ten per cent, supports the conclusion that the segment of the curve covering this range should be virtually a straight line. If the data of these investigators which give permeabilities greater than the equilibrium permeability are fitted with an equation of the form of (7), the coefficient *m* is observed to range from about 0.26 to 0.32. An increase in *m* with increased heterogeneity of the medium is also suggested. A summary of the permeability characteristics for media A through G together with four media studied by Wyckoff and Botset is presented in Table 2.

Probably the most significant factor influencing the variation in *m*, the change in relative permeability per unit change in air accumulation, is the size distribution of water-transmitting pores throughout the medium. In randomly packed uniform materials of constant porosity it is a fair approximation to assume that pores also are nearly uniform in size and that comparatively little water will reside in dead end or non-trans-

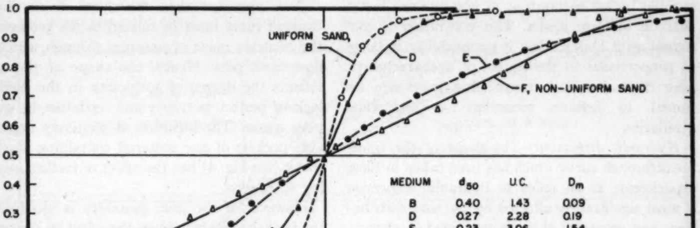

FIG. 7 – Effect of uniformity of grain size on hydraulic dispersion in saturated porous media

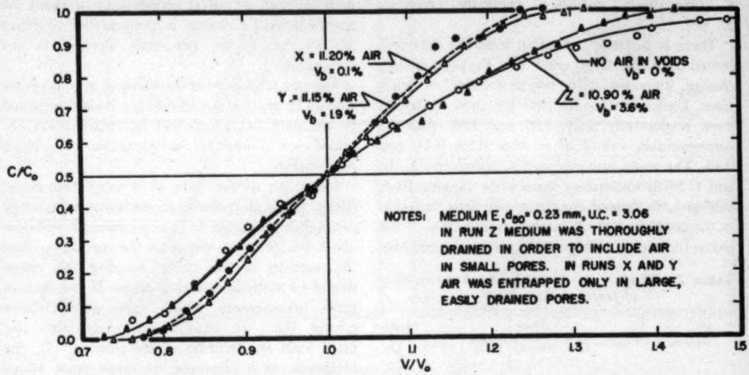

FIG. 8 – The effect of hydraulic dispersion of distribution of air in pore spaces of a porous medium

mitting pores. Accumulation of air in such a medium results in a fairly uniform alteration in pore geometry through the entire pore-size spectrum. The result, so far as permeability is concerned, appears to be a nearly linear reduction in permeability at a rate of about 26 pct per ten per cent change in air accumulation up to about 20 pct total air accumulation.

If, in non-uniform granular materials, bubbles tend to accumulate chiefly in the larger pore spaces there results a disproportionate change in the geometry of pore spaces. Hence, as can be seen from Figure 6, permeability is more severely restricted by air entrapment in non-uniform media than in uniform media. This conclusion is consistent with Darcy's law if permeability is taken as proportional to the square of a characteristic pore dimension and transmitting pores are assumed to behave somewhat as individual capillaries.

Hydraulic dispersion—The shape of the tracer breakthrough curve which has been taken in these experiments as an index to hydraulic dispersion is most significantly affected by the size, distribution, and geometry of pores contained in a representative unit volume of porous medium. Owing to the inherent complexities of porous-media systems, dependable methods of defining these parameters have not as yet been devised so it must suffice to relate dispersion characteristics to grain size and distribution and the effective porosity of the medium.

Comparison of many dispersion curves from columns of sand from the same parent stock showed that the size of medium *per se* had no influence on the shape of the curve. However, as the uniformity coefficient was increased the degree of dispersion, as indicated by the slope of the breakthrough curve, rapidly increased. Figure 7 shows the effect of non-uniformity on the shape of breakthrough curves for saturated sands of the same parent materials. The medium dispersion constant was noted to vary from 0.09 for a very uniform sand (uniformity coefficient = 1.43) to 2.79 for a sand with a comparatively wide range of grain sizes (uniformity coefficient = 3.88).

It is apparent that the shape of the breakthrough curve must be related to the geometry of the intricate maze of passages through which the flow must pass. Hence, the shape of the curve reflects the degree of tortuosity in the medium, lack of perfect isotropy, and variation in size of pore spaces. The inclusion of relatively impermeable pockets of fine material containing stagnant water (see Fig. 4) has the effect of further increasing dispersion.

However, if the pore geometry is modified by the inclusion of air bubbles the effect on dispersion is greatly dependent on the location of the bubbles. In Figure 8 are shown four dispersion curves for the same porous medium (sand E). Three of the curves represent tests in which the volumes of entrapped air was substantially the same (between 10.9 and 11.2 pct). The breakthrough curve for fully saturated flow is also shown for comparison.

In the case documented by curve Z, with 10.9

pct air entrapped in the voids, hydraulic dispersion was not greatly different from that produced by the fully saturated medium. This column was prepared for testing by subjecting the medium to draining under a tension of about 750 mm for one-half hour so that upon readmitting water many of the smallest pores probably contained air. The medium dispersion constant D_m for this case was estimated at 1.29 while that for saturated flow was about 1.54.

In cases X and Y with 11.2 and 11.15 pct air entrapped in the voids respectively, the breakthrough curves were much steeper, that is, dispersion was reduced. The medium dispersion constant D_m for these two cases was estimated at 0.72 and 0.71 respectively. Both of these columns were drained and rewetted in such a way that air was trapped primarily in the larger pore openings.

The apparent result of the selective location of air in the larger, more easily drained pores was to make more uniform the total aggregation of pores actually effective in water transmission; hence, the tendency of curves X and Y (Fig. 8) more nearly to approximate the shape produced by the highly uniform sand of Figure 7. For curve Z, on the other hand, each pore, large or small, received a more nearly proportionate amount of air. Such a distribution of air, while it isolated a larger fraction of the displaceable water volume (see point Z, Figure 3), produced a comparatively negligible effect on the distribution of pore sizes, probably translating the whole spectrum slightly in the direction of decreasing size.

When a small amount of air, say less than five per cent of the total void volume, was entrapped in only the larger pores the effect on hydraulic dispersion was not very pronounced. It is quite possible that inclusion of a small amount of air could have decreased the uniformity of pore spaces, thus increasing dispersion. In a few cases studied a slight increase in D_m was noted at low air concentrations. Experiments in this range were not easily duplicated.

Figure 9 summarizes the results of a series of tests performed on medium E, a fairly non-uniform material, in which the air content ranged from 0 to 14.3 pct of the total void volume. In each instance reported in the figure, air was entrapped primarily in the larger, more readily drainable pores.

An abrupt alteration in the shape of the breakthrough curve was apparent when the air content exceeded about five per cent. The steepening of the curves corresponds to a decrease in dispersion or D_m as can be seen from Figure 10 and reflects an increase in uniformity of the medium which is effectively transmitting the fluid. D_m decreased rapidly when the air content was more than 5 per cent, dropping from about 1.2 to less than 0.1 at about 14 pct.

An even more pronounced effect of air entrapment on D_m was noted for medium F (uniformity coefficient = 3.88). D_m dropped from 2.79 for a fully saturated medium to about 0.082 for a medium containing 15.3 pct air in the voids.

It is clear that the extent to which hydraulic dispersion is influenced by air entrapment is dependent on the location of air bubbles in void spaces and also on the structure of the porous medium. In systems where air may enter only the pore spaces; for example, in the practice of intermittent water spreading, it is to be expected that

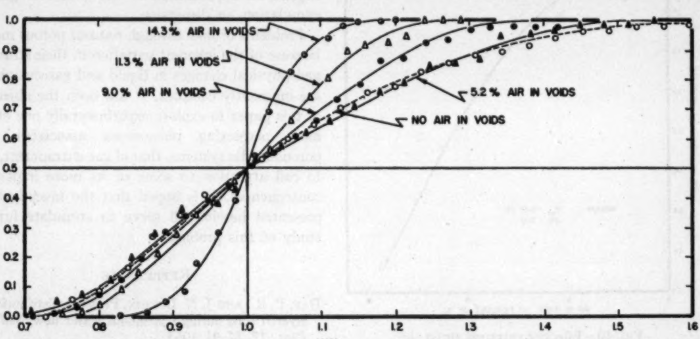

Fig. 9 – The effect of entrapped air on hydraulic dispersion in a porous medium

dispersion will be decreased as air is accumulated. On the other hand if air, or other gases, are liberated uniformly throughout pores of all sizes the effect on dispersion will probably be small. In general, the more nearly uniform is the medium, the less will be the influence of entrapped gas on dispersion. Also, in uniform media the location of gas accumulation, whether in large or small pores, appears to be unimportant.

Discussion—It is evident that comparatively minor modifications in the geometry of a porous medium by inclusion of a static gaseous phase can produce some rather significant changes in the hydraulic characteristics of the medium. These changes and the mechanisms through which they are accomplished have received some attention from soil scientists and physicists in the oil industry but seem to have been little appreciated in published technical literature and reference texts on ground-water hydrology.

A ten per cent accumulation of air in media void spaces may produce as much as 15 pct reduction in effective porosity of comparatively uniform materials such as were used in the studies reported herein. It is reasonable to expect that in more heterogeneous natural media, the isolation of pore volume by entrapped gases would be even more pronounced. Inasmuch as the estimation of velocities of water travel is dependent on porosity, it becomes important to evaluate properly the fraction of the medium volume which actually participates in the flow regime. Variations in time of flow or volume displacement may be, in part, accounted for by changes in effective porosity due to gas accumulations.

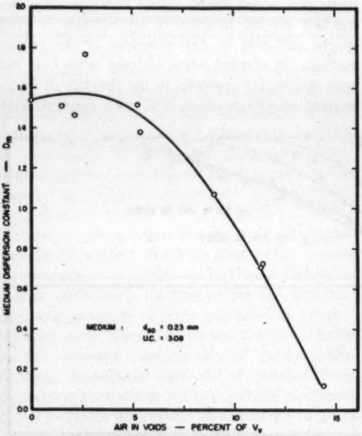

FIG. 10 – Effect of entraped air on the medium dispersion constant D_m

Changes in permeability caused by gas entrapment appear to be particularly important to the practical ground-water geologist or engineer. Variations in temperature and pressure from natural causes may bring about liberation or solution of gases in a natural formation with resultant changes in transmission characteristics. Artificial recharge of ground-water reservoirs by waste surface waters, or even certain industrial or domestic sewages, undoubtedly would induce some alterations in the gas content of an aquifer as a consequence of the bacterial or chemical characteristics of the recharge water. Since the permeability of a porous medium can generally be reduced more than 25 pct by a change in gas content of ten per cent it is apparent that gas entrapment could be an important factor in determining the potential capacity of an underground water supply or the practicality of a water reclamation scheme.

The increasing interest of engineers, geologists, and soil scientists in the mechanics of hydraulic dispersion and the more common use of ground-water tracers dictates a need for a better understanding of factors which control the shape of the dispersion or 'breakthrough' curve. The data presented in this paper show that gas entrapment may drastically alter the shape of the tracer curve. Proper interpretation of successive tracer studies on the same natural aquifer would unquestionably require an appreciation of the effects of gas accumulation on dispersion.

Problems of flow through natural porous media, because of the inherent variation in their structure and physical changes in liquid and gaseous phases are inherently complex. It has been the objective of this paper to explore experimentally one of the more perplexing phenomena associated with porous-media systems, that of gas entrapment, and to call attention to some of its more important consequences. It is hoped that the investigations presented herein will serve to stimulate further study of this problem.

Ground-Water Studies in New Mexico Using Tritium as a Tracer

HARO VON BUTTLAR AND IMMO WENDT

***Abstract*—A new method for ground-water investigations is described which employs tritium as a tracer. Tritium is produced in the atmosphere by cosmic radiation and hydrogen-bomb explosions, the latter causing large peaks in the tritium concentration of rain water. These peaks show up subsequently in underground water. Thus, an 'apparent' age of ground-water samples can be determined, enabling inference as to hydrological quantities such as the rate of flow of aquifers and the size of recharge reservoirs. To demonstrate the feasibility of the method, measurements were made on ground-water samples from New Mexico. Since the tritium content of the samples was extremely low, the tritium was enriched by electrolysis, and its concentration determined by the use of the low-level counting technique.**

Introduction—The problem of establishing sufficient water supplies for industry, agriculture, and domestic usage is rapidly growing more serious and may well become of basic worldwide concern if the present rate of population growth and economic development is maintained.

Conventional hydrologic determinations of the size and recharge of ground-water reservoirs and the properties of aquifers are often inadequate because of the complexity of the phenomena involved. New avenues of approach appear desirable, therefore, to supplement hydrologic studies, especially if thereby certain quantities become measurable which are beyond the reach of conventional techniques. The present paper describes such a method, together with some experimental results obtained by the New Mexico Institute of Mining and Technology. Advantage is taken of the circumstance that hydrogen-bomb tests in recent years have produced considerable quantities of radioactive water, the detection of which allows a determination of the 'apparent' age of the water.

The radioactive water constituent used in this research is tritium, the hydrogen isotope of mass 3, which has a half life of 12.5 years. Tritium is a nearly ideal tracer for ground-water studies because it is a part of the water molecule itself; further, its half life establishes a time scale between 0 and 30 years, which is convenient for the study of most ground-water problems [*Libby*, 1953]. It may be noted also that there is no radiation hazard in the use of tritium, because only small quantities are required with the very sensitive detection devices available, and because the maximum energy of the decay particle is only 18 kev. Thus no special precautions are required.

Tritium follows the flow of water without sufficient selective precipitation or absorption in the water-bearing formation to interfere with its use as a tracer. Tritiated water exchanges to a minor degree with water adsorbed on clay particles, as *Kaufman* and *Orlob* [1956] have demonstrated; the effect of the exchange, in their work, was to give the appearance of slower motion of the tritiated water through clay to the extent of about five per cent.

The work here reported makes use of tritium originating in the atmosphere as a tracer for subsurface waters. This tritium has two principal sources of origin. The first source is natural, inasmuch as tritium is formed by cosmic-ray bombardment of atoms in the upper atmosphere [*Currie* and others, 1956] and possibly also by direct accretion from the Sun [*Craig*, 1956]. Most of this tritium is oxidized and appears at the surface of the Earth in somewhat variable concentrations as a radioactive constituent of rain water. The concentration of tritium produced by natural means and associated with rain at the Earth's surface will depend upon the trajectory and general history of the water vapor involved. Values of the order of one tritium atom in 10^{17} water molecules have been found by Libby and coworkers [*Kaufman* and *Libby*, 1954; *von Buttlar* and *Libby*, 1955].

The second important source of tritium in the atmosphere is the thermonuclear reactions provided by hydrogen-bomb tests. Although the concentration of tritium produced by bomb explosions as observed in rain and surface water will exhibit at first the geographical spottiness characteristic of atmospheric contamination from such sources, the result soon becomes widespread and hemispheric in its extent. Thus the tritium content of surface waters has been raised quite generally by a factor of from 10 to 100.

The first thermonuclear explosion (March 1954)

provided a relatively sharp and distinct marker for rain water falling in the northern hemisphere. Shortly after the explosion, the tritium content of this water attained a peak and subsequently returned almost to the prebomb level within a few months. A second series of bomb tests provided another tritium peak in 1956. Libby and coworkers [*Kaufman* and *Libby*, 1954; *von Buttlar* and *Libby*, 1955; *Begemann* and *Libby*, 1957] have monitored rainstorms at Chicago since 1952. Their data are plotted in Figure 1 to show the variation of tritium concentration with time. Similar results have been found for rainfall at Ottawa, Canada, by *Brown* and *Grummitt* [1956]. Available data indicate that New Mexico rains exhibit approximately the same variations (see Table 1 and the worldwide data reported by *Begemann* and *Libby* [1957]).

Radically different concentrations of tritium result from these atmospheric sources (see Fig. 1). The following criteria can thus be established for the proposed use of atmospheric tritium in the study of ground water:

(1) Water with unmeasurable tritium content may be said to be old; that is, to have been underground more than approximately 30 years and to be unmixed with recent meteoric water.

(2) Water under the ground before 1954 and unmixed with recent meteoric water can be dated within limits imposed by the radioactive decay rate, and with an accuracy determined by the range of variability of natural tritium contamination and the accuracy of the measuring technique

In a similar way *Kaufman* and *Libby* [1954] have dated wines of different vintages.

(3) Water containing a large amount of tritium relative to that expected from cosmic-ray sources in natural rain can be said to be recent; that is, to have a surface origin since 1954, or to have been strongly mixed with recent surface water.

(4) In some cases, where detailed information is available concerning the tritium concentration of underground water as a function of time, the peak in tritium concentration caused by a bomb explosion can be utilized to fix with reasonable precision the time of origin of the water as surface rain. Such data can be used also to infer the rate of flow of the water and the size of the reservoir into which the bomb tritium has been mixed.

Even though the measuring techniques for the tritium concentration of water have been perfected to such an extent that the error of a single measurement is of the order of ten per cent, it must be kept in mind that the interpretation of the data as to their hydrologic significance is likely to be difficult. It is the intent of this paper, therefore, to point out the type of problem which can be attacked rather than to present a completed areal hydrologic study.

The conduct of thermonuclear reactions which produce tritium in the free atmosphere may impose definite limitations in the future upon the techniques employed for tracing water by the use of atmospheric tritium. Under conditions of more frequent bomb testing, a peak found in ground water could not be attributed with certainty to a particular thermonuclear reaction.

Apparatus—Even though testing of a large bomb may increase the tritium concentration of the atmosphere many fold over that due to natural causes, the concentration expressed as a ratio of tritium to protium (hydrogen of mass 1) will be extremely small; of the order of 10^{-16}. *Kaufman* and *Libby* [1954] and *von Buttlar* and *Libby* [1955] have described apparatus and outlined procedures for enriching the tritium in water by electrolysis, and for measuring its concentration by the use of the low-level counting technique. The apparatus employed at the New Mexico Institute of Mining and Technology is similar to that used by Libby and coworkers. Although each sample requires two months of electrolysis time, many samples (in our case 25) can be processed concurrently.

Measurements of the amount of tritium are not affected by impurities in the water or by the type of storage vessels used, since the water samples are distilled several times preparatory to making the final measurements.

The relationship $T/T_0 = (V_0/V)\,(DV/D_0V_0)^{\alpha/\beta}$ holds between the tritium enrichment and the deuterium enrichment in the process of electrolysis. The symbols used are:

T	tritium concentration of the enriched sample as measured by its level of radioactivity
T_0	tritium concentration in the sample prior to electrolysis
V	volume after electrolysis
V_0	volume before electrolysis
D	deuterium concentration of the enriched sample
D_0	deuterium concentration before electrolysis
α	separation factor for deuterium
β	separation factor for tritium

The ratio β/α is believed to be constant; its value was determined by Kaufman and Libby to be 2.1 ± 0.1.

In the present study, values taken for V_0 varied from 2 to 6 liters; values for V between 0.2 and 0.3 ml. The quantity D was determined by the falling-drop method as described by *Kirschenbaum* [1951]. The initial deuterium concentration is known to vary somewhat in nature [*Friedman*, 1953], but for the present work an average value of 0.0142 mole per cent is assumed.

Geiger tubes of effective volume of about 0.425 liter are filled to 2 cm mercury pressure of ethylene, 3 cm of argon, and 5 to 20 cm of sample hydrogen, to determine the tritium activity of the enriched sample. Good plateaus of several hundred volts length in the neighborhood of 1300 v are obtained through the use of an electronic quench circuit with eight milliseconds dead time after each pulse. The counters are surrounded by a ring of 11 anticoincidence counters, and the entire arrangement is shielded by six inches of steel. The background of the sample counters when filled with unenriched hydrogen is 155 counts per minute without, and 18 counts per minute with, the anticoincidence ring in operation. Experiments are in progress to reduce the background further.

Comparison with the same tritium standard used in the Libby laboratory indicates that one count per minute per cm pressure of hydrogen gas in the counters used at this laboratory corresponds to 3.5×10^4 T units, the T unit being defined as a tritium concentration of 1×10^{-18} atoms of tritium per atom of protium.

It is estimated that the overall error in each

tritium assay is about 10 pct; certainly not higher than 15 pct. This error can be tolerated in view of the large tritium-concentration difference in the samples investigated. If a sample count of 1 cpm/cm pressure of hydrogen can be distinguished from the background, the detection limit at a tritium enrichment of 10^4 is 3.5 *T* units. Actually, samples having a smaller activity can be counted, but the error of the measurement may then exceed 10 pct because of the inherent uncertainty connected with the background when gas counting is employed.

Illustrations of the application of the tritium method to ground-water samples—The simplest problem which can be solved by the application of the tritium method is that of determining the 'apparent age' of a water sample. As stated above, water containing less tritium than the detection limit of the apparatus has an age greater than about 30 years, whereas water containing more tritium than the prebomb natural level has an apparent age of less than three years, even though it may be a mixture of older water with water less than three years old which contains bomb tritium. Water, on the other hand, which has a tritium concentration of between 0 and, say, 10 *T* units has an apparent age of between 3 and 30 years, even though it may represent a mixture of older and younger waters.

Water definitely younger than three years was found in a sample from an oil well in Wyoming (Table 2, sample 66), where water flooding is employed for secondary recovery. This showed clearly that the water pumped from the well was derived from the injection water. The implications of this measurement will be discussed more fully in a separate paper.

Samples from the Carlsbad Caverns reveal fairly recent origin of the water. The King's Palace sample (Table 2, No. 90), which shows a relatively high tritium concentration, indicating the presence of bomb tritium, has an apparent age of less than three years; the sample from the left wing (Table 2, No. 91) shows an apparent age of between three and 30 years. Both samples definitely contain water of fairly recent origin.

Tritium determinations also can provide information concerning the process of recharge of underground aquifers. It is reasonable to expect some tritium to be present in the near-surface layers of ground water originating from rainfall with elevated tritium content, the tritium concentration being related to the degree of recharge.

Samples of three wells (Table 2, No. 54, 55, 92) from Circle Mesa quadrangle, Silver City, New Mexico, were selected to study this relationship. These wells are drilled into the Tertiary(?)-Quaternary alluvium. The samples were collected on April 25, 1956, a time when, owing to the 1956 bomb tests, the tritium content of the rain water was well above the background level.

The well from which sample 92 was taken is 250 ft deep and shows no depth-to-water fluctuation during the past two years, indicating very little local recharge. The tritium content is low.

The depth to water of the well from which sample 55 was taken has varied between 28 and 65 ft during the past two years, indicating appreciable local recharge. This sample shows a relatively high concentration of tritium.

The third well has fluctuated between 89 and 96 ft during the same period of time, corresponding to a moderate amount of local recharge. The tritium content found in sample 54, from this well, was intermediate to those of the other wells.

These findings are consistent with the assumption that the tritium technique yields information as to the extent of local recharge.

An interesting type of ground water is that discharged by hot springs. Libby and coworkers have analyzed the water from hot springs from a number of different areas. They conclude that such springs generally contain water of recent meteoric origin.

A spring of this kind provides the principal source of the municipal water supply of Socorro, New Mexico. The city obtains its water from two sources, a hot spring and a well. The spring is located about 1.5 mi west of the well; its ground elevation (4890 ft) is about 150 ft higher than the well. It is believed [*Waldron*, 1956] that the spring derives its water from the ground-water table in the Snake Ranch Flats (close to Socorro Mountain, 5800 ft), which is recharged from the Magdalena Mountains situated about ten miles west of Socorro. The water probably travels through a permeable zone, or through fractures under Socorro Mountain, and rises along a major fault which coincides with the eastern limits of Socorro Mountain. The well, on the other hand, taps the Rio Grande water table and does not receive a large contribution from the water feeding the spring.

^{a} Samples for which the error of the measurement probably exceeds 10 pct.

The spring water would require a considerable period of time to travel underground from the Magdalena Mountains to the spring site, whereas the Rio Grande valley receives recharge mainly along the valley walls and through the river itself. The well, situated near the valley walls, would therefore be expected to discharge water with elevated tritium concentration sooner than the hot spring.

Assuming that the tritium value in November 1956 represents bomb tritium in the well only, it follows from the data of Table 3 that the bomb peak had not yet appeared in the hot-spring

[a] Except Well No. 3, 1955.

water. This would indicate an average velocity of the water feeding the spring of less than ten miles in three years, or less than 50 ft/day. Further monitoring of the hot-spring water may reveal a peak in the tritium concentration from which, among other quantities, a value for the velocity of flow can be determined.

The fact that the well water shows considerably less tritium in early 1957 than the Rio Grande water indicates that the river water does not mix immediately with the entire ground water. Tritium determinations on waters from other wells in the valley should reveal information concerning the mixing rate.

The relatively few examples discussed above indicate the versatility of the tritium method when applied to ground-water problems. Even a single measurement may provide information which is difficult to obtain by other means. It should be kept in mind, however, that in general a ground-water table represents by no means a simple system. More detailed studies, therefore, are necessary before the hydrology of a larger area can be understood. An investigation of this kind is discussed in the next section.

Tritium study of wells near Carrizozo, New Mexico—Rain or river water entering the underground system at the recharge areas subsequently flows underground with a velocity proportional to the inclination of the water table and to the permeability of the formation. At the instant of recharge, the tritium concentration is identical with that of the surface water in the area. During subsequent underground flow, radioactive decay and mixing with older water diminish the tritium concentration. The detection of the bomb peaks in the tritium concentration of wells along the downslope of mountains should reveal information concerning the rate of water flow from the recharge area to the well site, provided no recharge takes place along the downslope. If the recharge area is known and can be approximated by a point or a line, the rate of flow can be inferred, for example, from the time of appearance of the 1954 or 1956 peak in tritium concentration at a well site of known distance from the area of recharge or at two wells of known distance apart. Also, the peak height enables one to infer the size of the ground-water reservoir into which the tritiated water has mixed.

In order to determine the applicability of the tritium method to the problem of ground-water flow, an area south of Carrizozo, New Mexico, was selected for study (see Fig. 2). Chemical analyses of these waters are shown in Table 4. This area was chosen for the following reasons:

(1) Recharge is believed to occur mainly in the mountain range lying to the south.

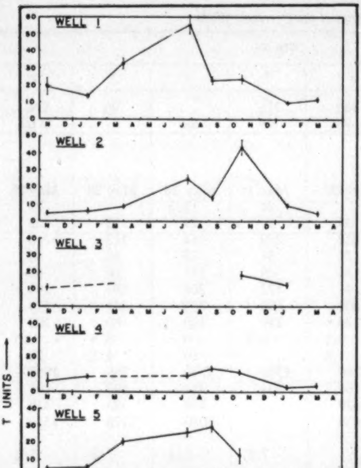

FIG. 3 – Tritium concentration peaks found in the test wells of the Carrizozo area

(2) The water table is inclined to the northwest and drops about 0.1 mile per mile, so that a reasonably high flow rate may be expected.

(3) Until very recently, no large quantity of water was pumped from the aquifer for irrigation purposes. The tested wells are all stock wells, with the exception of the municipal well of Carrizozo, which is pumped at the rate of 200 – 600 gallons per minute. Thus, recycling of irrigation water does not occur.

(4) The municipal water supply of Carrizozo presents a serious problem as to its quantity and quality. Investigations using the tritium method may be helpful to this community.

The area has been subjected to various types of geophysical exploration by the New Mexico Institute of Mining and Technology. A preliminary report by *Weber* and *Holmes* [1951] describes briefly the geological environment and lists resistivity measurements of the ground. It is apparent from their work that the valley contains two groups of water-bearing formations. The upper horizon consists of Quaternary alluvium having a saturated thickness of about 100 ft below the water table, which in turn lies at a depth approximately 100 ft below the land surface. The bedrock consists of Cretaceous sandstone and shale, the sandstone beds carrying low-quality ground water. These beds crop out near the 5300-ft contour line east of the village of Carrizozo, as evidenced by a number of perennial springs.

Samples for the tritium analysis were taken from the eight wells shown in Figure 2 at intervals of two to three months. Wells 1, 2, 5, 6, and 7 are shallow and tap only the alluvial water table. Wells 3, 4, and 8 are deeper and probably penetrate into the Cretaceous beds. Only well 4 (the municipal well) is heavily pumped. Wells 1, 2, 5, 7, and 8 are stock wells; wells 3 and 6 were not used during the time of the investigation.

As seen from Figure 3, marked peaks occurred during the summer and fall of 1956 in most of the wells investigated. Two interpretations are suggested:

(1) It may be assumed that the peaks represent the 1954 bomb tritium which went underground on the forested mountaintops to the south and southeast. If this is the case, well 1 should reach its tritium maximum first. The three wells 2, 5, and 6 should follow next; then well 7, well 8, and finally wells 3 and 4. It is obvious that well 1 had its peak before any other well, most of the others following approximately in the order indicated. Well 4 did not exhibit a marked peak. Insufficient data were obtained to determine whether or not a peak occurred in well 3. Further observation will show whether wells 3 and 4 will show their peaks at a later time. The interpretation of the wide peak found for well 8 is difficult. Possibly this water represents the mixing of water from two or more sources having different tritium concentrations caused by dissimilar trajectories. This is possible, since the well is deep and taps several water layers.

The average peak height exhibited by the wells was about 50 *T* units, with surprisingly little variation. The average peak tritium concentration of rainfall during the summer of 1954 was about 500 *T* units. This would mean that the 1954 recharge had to be diluted ten-fold in the ground-water reservoir. The ground-water inventory, therefore, must be at least ten times the amount of recharge in that year.

The width of the well peaks, except for well 8, is of the same order of magnitude as the tritium peak found in the 1954 rainfall (see Fig. 1). This would indicate that the underground flow is fairly uniform.

On the assumption that the peaks are due to the 1954 bomb test, the time lag occurring between the maxima of the peaks for the different wells is compatible only with a flow rate in excess of 50 ft/day. Insufficient data concerning the rate of flow of water through the water-bearing strata of this area are available to determine whether or not this is a reasonable value.

(2) Another possible assumption is that the well peaks represent the 1956 tritium peak of rain that found its way into the ground water soon after it fell. This would mean that direct recharge of the aquifer occurs along the downslope. All the wells might be expected to have their peaks at the same time shortly after the rainfall containing a high tritium concentration had occurred. In this case the occurrence of peaks would not be related to the lateral velocity of the ground-water motion. Further detailed studies will be required, however, to reveal the rate of percolation of surface water into the aquifer.

If an average value of 300 *T* units is assumed for the 1956 summer rains, the well-peak maxima of about 50 *T* units would indicate that the water pumped from the wells in the fall of 1956 contained recent rain water to the extent of 10 to 20 pct. Water-table-fluctuation determinations, if available, would indicate whether or not this is possible. It is strange that all the wells that exhibit peaks should mix to approximately the same degree even though they are of different depths.

The peak width of the tritium-concentration curves for the wells is of the same order of magnitude as the peak width of the 1956 rainfall curve. The delay of the peak maxima of the wells with respect to the rainfall may be related to the time required for percolation through the overburden of the aquifer. As most of the rainfall occurred in July and August (see Fig. 4), the data indicate a rate of percolation of approximately one foot per day.

The fact that the well peaks are sharp and drop rather quickly in early 1957 to values comparable to prebomb rain water is difficult to understand if the peaks are due to the 1956 bomb test. The vertical percolation with subsequent lateral motion should have caused peaks of greater duration. Only if the vertical diffusion of tritium through the aquifer is very rapid (about 10 cm/day) and is the rate-determining factor, can the shape of the peaks be explained. The rainfall at the nearby city of Ruidoso, which is situated at about the same altitude as the Carrizozo sampling sites, and where the amount of rainfall is similar, is plotted in Figure 4. The scanty precipitation between August 1956 and February 1957 may account for the return of the tritium concentration to such low values.

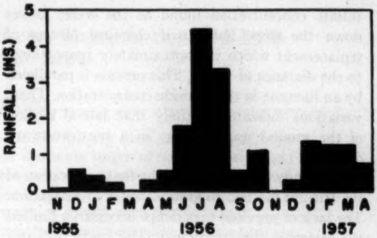

FIG. 4 – Official rainfall data for Ruidoso, N. Mex., taken from the New Mexico *Climatological Data* [U. S. Weather Bureau]

Arguments against this interpretation are that the total mixing would have to be the same for every well, as indicated by the similar peak heights, and that well 8, even though it is very deep, reaches the same maximum value.

From these considerations it appears likely that the tritium peaks exhibited by the ground water are those of the 1954 rainfall, although additional data are needed before final conclusions can be drawn.

Chemical analyses (Table 4) were obtained of the waters from all wells except 5, which recently has been dismantled. The chemical analyses show that the total amount of solids dissolved in the water generally increases toward the valley. The only exception is well 6; this may be due to stagnation of the water in the unused well or to a local high concentration of soluble materials in the soil. A high nitrate concentration in wells 6 and 8 possibly indicates greater surface-water contamination. The calcium and bicarbonate concentrations found in all the wells indicate that the water has previously moved through a limestone layer. The gradually decreasing bicarbonate and increasing sulfate concentration found as the water moves down the slope indicate a chemical process of replacement which is approximately proportional to the distance of travel. This process is paralleled by an increase in the chloride concentration. These variations indicate definitely that lateral motion of the ground water occurs in a northwestward direction.

The study at Carrizozo is the first application of the tritium method to ground-water investigation. The lack of previous experience necessarily limited the design of the experiment. The study indicates that the following factors should be kept in mind for future work:

(1) The simplest problem of analysis with reference to the rate of flow obtains where the wells in question tap only one ground-water layer. Otherwise the pumped water may be a mixture of waters of varying age from different levels, since perforated well casings sample a considerable vertical range of the aquifer. In this case, nevertheless, inference can be drawn as to the presence and character of the different water layers.

(2) For the investigation of ground-water flow, there should be reasonable evidence that no recharge of the aquifer occurs between the wells under investigation. On the other hand, if recharge occurs, the rate and extent of percolation can be determined.

(3) Areas which are heavily pumped for irrigation purposes, and where recycling of the irrigation water may obscure the tritium concentration peaks, should not be used for the determination of flow velocity. The extent of recycling can be inferred, however, from tritium measurements.

(4) In order to establish more accurately the time, height, and width, of the tritium peaks, a more frequent sampling schedule than that used in the present study is recommended. It is not necessary, however, that all samples be analyzed, since frequent samples are of value only at or near the peaks.

Factors Affecting Sediment Delivery Rates in the Red Hills Physiographic Area

SAM B. MANER

Abstract—Twenty-five records of watershed sediment delivery rates and factors affecting sediment-delivery rates are analyzed. Relief and maximum length of watershed expressed as relief-length ratio (R/L) in a simple curvilinear correlation or as individual variables in a multiple curvilinear correlation are found to offer a much closer correlation with sediment-delivery rates than size of sediment contributing area or several other factors tested.

The basic trend of thought in this study is that rates of sediment yield of watersheds are immediately comparable only if their gross erosion rates per unit of area are the same. Otherwise, it is their delivery rates that must be compared, and once causal factors of the sediment-delivery rate have been evaluated for a soil and climatic region, it is possible to predict sediment yields closely from gross erosion data and the delivery rate characteristics of individual watersheds within that region.

Introduction—This paper presents the results of sediment-delivery rate studies of a group of reservoirs and their watersheds in the Red Hills physiographic area, a sub-division of the central lowlands province in extreme southern Kansas, western Oklahoma and western Texas (Fig. 1). The area corresponds generally to the Rolling Red Plains land resource area.

Sediment delivery rates have been investigated in the Blackland Prairies of Texas and the Loess Hills in eastern Nebraska, western Iowa, southwestern Minnesota and southeastern South Dakota. *Maner* and *Barnes* [1953], in a study of the Texas Blackland Prairies, found that the size of net sediment contributing area is an excellent indicator of the delivery rate of watersheds within a given size range. In fact, difference in size of net sediment contributing area accounted for approximately 93 pct of the variation in sediment-delivery rates between a group of watersheds ranging in size from 0.43 to 8.71 sq mi. The results of that study indicate uniformity among other watershed characteristics which have an influence on sediment delivery rates in that physiographic area. To demonstrate the fact that variables other than size of net sediment contributing area may have an important bearing upon sediment delivery rates, *Glymph* [1954] developed a delivery rate equation from Loess Hills sedimentation data previously presented by *Gottschalk* and *Brune* [1950]. In this case difference in size of net sediment contributing area explained only 18 pct of the variation in sediment delivery rates of a group of watersheds ranging in size from 0.038 to 41.3 sq mi. The results of his study indicate that unless factors which influence sediment delivery rates are uniform for all watersheds, within a given area, the ratio of sediment yield to gross erosion may be expected to show considerable variation for equal size sediment contributing areas even within the same physiographic area.

Sediment delivery rate, defined by *Glymph* [1954], as the ratio between annual sediment yield and annual gross erosion, is dependent upon a number of watershed factors and the study presented here has been undertaken to develop a procedure in which measurable watershed characteristics are used to make acceptable estimates of sediment delivery rates. The factors tested include length, relief, shape, size of net sediment contributing area, weighted average land slopes, channel density, and relief-length ratio.

The study included the following six steps: (1) tabulation of existing reservoir sedimentation survey data after making adjustments for reservoir trap efficiency and size of net sediment contributing area to determine total sediment yield and rate of sediment yield per square mile of net sediment contributing area, (2) estimation of gross erosion rates during period of sediment record, (3) sediment delivery rates were computed from data obtained in steps (1) and (2), (4) detailed studies were made of the watershed of each reservoir to assemble quantitative data on physical characteristics which were thought to influence downstream delivery of eroded material, (5) data obtained in step (4) were correlated with sediment delivery rates to develop a regression equation for estimating sediment delivery rates and (6) after developing the best equation for estimating

sediment delivery rates, a study was made to determine the characteristics of the independent variables used in the equation.

Sediment yield data—Twenty-five reservoirs on which sedimentation survey data are available were selected for use in developing the watershed sediment-yield values used in this study. Other reservoirs in this physiographic area were eliminated from the study for one or more of the following reasons: net sediment contributing area of more than 350 sq mi, breached dam during period of sediment record, doubtful trap efficiency of reservoir, and inaccuracy of reservoir sedimentation survey data, judged principally on the method of survey used. For example, reconnaissance surveys with only a few random observations throughout a reservoir were not considered to be within the range of accuracy adopted in this study. The sample reservoir locations are shown in Figure 2.

[a] Excluding area of reservoir and the combined drainage areas of average number of stockponds in watershed during period of sediment record.

[b] Stockpond.

Sediment-yield values for the sample watersheds were established by adjusting measured reservoir sediment production rates for reservoir trap efficiency and net sediment contributing area. In estimating the trap efficiency of each reservoir, the method based on capacity-inflow ratio (C/I) developed by *Brune* [1953] was used. The net sediment contributing area of each watershed was determined by substracting reservoir area and average total area behind upstream stockponds from the total drainage area. Sediment contributing areas range from 0.036 to 332 sq mi; however, 64 pct of the reservoirs have sediment contributing areas of less than 15 sq mi.

Sedimentation surveys of the sample reservoirs were made by the Soil Conservation Service during the period from November 1937 to March 1955. The ages of the reservoirs (length of sediment record) at the time of survey ranged from 3.7 to 41.0 years with an average age of 19.0 years. Only three of the reservoirs (records 5, 15, and 18) were under five years of age at the time of survey; therefore, sediment yield values are thought to be representative of the long-time mean. Table 1 gives the location, size of net sediment contributing area, period of sediment record and length of sediment record of each reservoir studied. Column 5 of Table 2 gives the sediment yield values of each reservoir watershed.

Gross erosion rates—Studies were made of the watershed above each reservoir to develop data for estimating the annual rate of gross erosion per square mile of net sediment contributing area. This rate was estimated by computing separately the amount derived from sheet erosion and the amount derived from channel erosion.

The average quantity of material derived from channel erosion, including gullies, was estimated from watershed channel density data and data on annual rates of channel enlargement obtained by comparing channel development on early and recent watershed aerial photographs (period between photographs varied from 8 to 16 years).

Annual sheet erosion rates were computed by the *Musgrave* [1947] method in a manner previously described by *Barnes* and *Maner* [1953]. According

to Musgrave's findings, based on data from 19 widely scattered research stations, annual soil loss rate from sheet erosion is a function of the inherent erodibility of the soil, degree of land slope in per cent, length of land slope in feet, cover factor and maximum 30-minute rainfall, two-year frequency, in inches. As a result of his findings, soil loss from sheet erosion can be expressed by the equation

$$E = FRS^{1.35} L^{0.35} P_{30}^{1.75} \qquad (1)$$

where

E = sheet erosion, inches per year
F = soil factor, basic erosion rate, inches per year
R = cover factor
S = land slope, in per cent
L = length of land slope, in feet
P_{30} = maximum 30-minute rainfall, two-year frequency, in inches

Estimated annual rates of gross erosion per square mile of net sediment contributing area are shown in Table 2, Column 3.

Delivery rate—The rates of sediment yield of watersheds are immediately comparable only if their gross erosion rates per unit of area are the same. Otherwise, it is their delivery rates that must be compared. This may be observed, for example, from the records of two watersheds (record 7 and record 25) with almost identical rates of sediment yield of 1087 tons and 1066 tons, respectively, per unit of area. If the watershed with a rate of sediment yield of 1087 tons has an erosion rate of 5335 tons, its yield-erosion ratio is 0.20, while if the watershed with a rate of sediment yield of 1066 tons has an erosion rate of 1728 tons its yield-erosion ratio is 0.59. Although rate of sediment yield is practically the same for both watersheds the great difference in yield-erosion ratios should correspond to proportional differences in watershed characteristics. Based on this reasoning, the ratio between annual rate of sediment yield and annual gross erosion rate per square mile of sediment contributing area was computed for each watershed. This ratio, called the delivery rate, is expressed in per cent, and treated as the dependent variable in the correlation analysis of data. Table 2, Column 6 shows the sediment delivery rate of each watershed.

Watershed physical surveys—Detailed studies were made of the watershed of each reservoir to assemble quantitative data on physical characteristics which were considered to influence downstream delivery of eroded material. The variables studied are: (*S*) size of net sediment-contributing area in square miles; (*CD*) channel density, miles of channel per square mile of net sediment-contributing area; (*L*/*W* ratio), the ratio between maximum length and average width of watershed was considered as a shape factor; (*WS*) weighted average land slopes in feet per hundred feet; (*R*) watershed relief in feet defined as the difference in elevation between the average elevation of the watershed divide at headwaters of mainstem drainage and elevation of streambed at dam-site; (*L*) maximum watershed length in feet, measured approximately parallel to mainstem drainaged from dam-site to watershed divide and (*R*/*L* ratio) relief-length ratio (essentially the same as relief ratio as defined by Schumm [1954]) computed by dividing (*R*) by (*L*) for each watershed. Table 3 shows numerical values for each variable and the source of information.

Analysis of data—Correlation analyses were made in order to determine the relationship between sediment delivery rate and selected measurable watershed characteristics. In the analyses,

delivery rate, expressed as the per cent of the annual gross erosion delivered to the reservoir, was treated as the dependent variable. Variables listed under watershed physical surveys were all considered as independent and were tested individually, in association with each other and in some cases two variables were combined and expressed in ratio form. The statistical method of analysis has been outlined by *Croxton* and *Cowden* [1953] and *Snedecor* [1940].

A scatter-diagram plotting of sediment delivery rate against each independent variable showed a definite departure from linearity in most cases. Similar plottings on logarithmic ruled paper indicated that the exponential growth curve would adequately describe the characteristics of the data. Thus, the numerical values of all variables were transformed either to logarithms or cologarithms for use in the regression analyses.

A study of the various plottings on log paper revealed that maximum length of watershed and relief of watershed when expressed as relief-length ratio plotted best with sediment delivery rates. Therefore, a non-linear correlation between relief-length ratio and sediment delivery rate was computed as the initial step in statistical analysis of the data. The regression equation for this correlation is

$$\log DR_e = 2.94259 - 0.82363 \text{ colog } R/L \text{ ratio} \quad (2)$$

where

DR_e = estimated sediment delivery rate in per cent of annual gross erosion

R/L = relief-length ratio

The standard error of estimate of (2) is ±0.04041 log units, and the coefficient of curvilinear correlation 0.987, which expresses a 97 pct account of the variation in sediment delivery rates. The empirical relationship of sediment delivery rate to relief-length ratio is presented in the form of the delivery rate curve Figure 3.

To determine the relative influence of relief and length of watershed, as individual independent variables, in estimating sediment delivery rates a multiple curvilinear correlation between these three variables was computed. The regression equation for this correlation is

$$\text{Log } DR_e = 2.96162 + 0.86868 \text{ Log } R - 0.85354 \text{ Log } L \quad (3)$$

where

DR_e = estimated sediment delivery rate in per cent of annual gross erosion

R = relief of watershed, in feet

L = maximum length of watershed, in feet

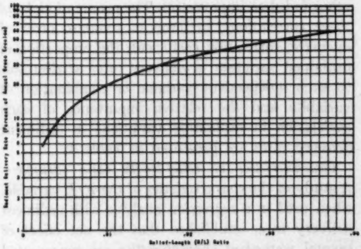

FIG. 3 – Sediment delivery rate curve

TABLE 4—*Results of cnrviliuear correlation analyses; dependent variable, sediment delivery rate*

Independent variables	Standard error of estimate	Coefficient of curvilinear correlation	Proportion of explained variation	Explained variation index
	log unit		pct	
Relief-length ratio (R/L)	±0.0404	0.987	97.3	1.00
Relief and length	±0.0537	0.979	95.8	0.98
Length	±0.1500	0.795	63.2	0.65
Length-aver. width ratio (L/W) and net contributing area	±0.1756	0.746	55.6	0.57
Net sediment contributing area	±0.1733	0.714	50.9	0.52
Length-aver. width ratio (L/W) (shape)	±0.2082	0.540	29.1	0.30
Relief	±0.2190	0.465	21.6	0.22
Weighted aver. land slopes	±0.2195	0.460	21.1	0.21

The standard error of estimate of (3) is ± 0.0536 log units, and the multiple correlation coefficient 0.979, which explains approximately 96 pct of the variation in sediment delivery rates. In this particular correlation when length of watershed is ignored or held constant the total correlation between relief and sediment delivery rate is −0.46509. On the other hand when relief is ignored or held constant the total correlation between length of watershed and sediment delivery rate is −0.79508. Further statistical manipulation of the results of this correlation revealed that length of watershed is approximately 1.5 times as effective in estimating sediment delivery rates as is watershed relief.

Subsequent testing of other independent variables individually and in association with each other failed to improve (2). The results of eight of these correlations, in terms of standard error of estimate, correlation coefficient, the proportion of explained variation in delivery rates attributable to each independent variable or combination of variables and the relative importance of each correlation in explaining variations in sediment delivery rates are presented in Table 4.

Characteristics of relief-length ratio variable—A study of the characteristics of the *R/L* variable, when used in a regression analysis with sediment delivery rate, established that the net effect of several watershed characteristics are represented in the derived equation for estimating delivery rate. For example, plottings on logarithmic paper revealed that *R/L* is related to the following measurable watershed factors: (1) Size (net sediment-contributing area). Large watersheds usually have lower *R/L* than smaller watersheds in the same area. (2) Shape (length-width ratio). Short, wide watersheds usually have higher *R/L* ratios than long narrow watersheds. (3) Alluvial soils area-net watershed area ratio. In contrast to high *R/L* ratio watersheds, low *R/L* ratio watersheds have a greater proportion of their total area in alluvial soils, indicating the positive influence of low *R/L* ratio watershed characteristics on upstream deposition. (4) Average land slopes. Generally high *R/L* ratio watersheds are associated with steep land gradients. (5) Average stream gradients are directly related to *R/L* ratio values. (6) Channel density. Generally greater channel density per unit of area is associated with higher *R/L* values.

Conclusions—(1) Sediment delivery rate in the Red Hills physiographic area is a function of several watershed characteristics which are related to and apparently adequately expressed by the variable relief-length ratio. However, the validity of the use of this variable in other areas must be established by adequate testing.

(2) Maximum length of watershed is approximately 1.5 times as effective in forecasting sediment delivery rates as is watershed relief.

(3) The influence of the maximum length of watershed on sediment delivery rate is conditioned by the total relief associated with maximum length. Likewise, the influence of a given watershed relief value on sediment delivery rate is conditioned by the distance eroded materials must travel between the high and low points used in computing watershed relief.

(4) The relatively close estimation of the per cent of gross erosional material delivered to a reservoir site from relief-length ratio data demonstrates that the rate of sediment yield to a structure site is subject to acceptable estimation, in the Red Hills physiographic area, if certain physical characteristics of the watershed are incorporated in the estimate and the gross erosion rate is known or can be computed.

Effect of Temperature Distribution on Moisture Flow in Porous Materials

W. WOODSIDE AND J. M. KUZMAK

Abstract—Several experimenters have observed moisture flow rates through porous materials under a temperature gradient, which are many times the calculated rates based on vapor diffusion. To investigate this discrepancy, a temperature gradient was applied across an enlarged model of a particular, high-quartz wet sand, and the temperature distribution within the pore spaces was measured. For the 'air-dry condition' of the model, the average temperature gradient in the pore spaces was six times the over-all applied gradient. Approximately this same ratio exists, therefore, between the respective vapor pressure gradients.

It is proposed that the flow mechanism consists of multiple vapor diffusion and liquid flow steps in series, the resistance to flow in the liquid phase being negligible, so that the flow rate is determined by the vapor pressure gradients in the pore spaces. The fact that these gradients are of the order of six times the over-all gradient previously used to calculate the flow rate at least partially explains the discrepancy.

Introduction—The mechanism by which water moves through a porous material when subjected to a temperature gradient has not yet been definitely established [*Bouyoucos*, 1915; *Smith*, 1943; *Winterkorn*, 1947; *Gurr* and others, 1952; *Taylor* and *Cavazza*, 1954]. The experimentally observed rate of flow from the hot to the cold side is found to be about ten times the calculated rate based on vapor diffusion [*Bouyoucos*, 1915; *Winterkorn*, 1947; *Taylor* and *Cavazza*, 1954]. It has been suggested that this lack of agreement between the experimental and calculated rate occurs because some of the water flows in the liquid (film) phase [*Winterkorn*, 1947].

Experiments designed to detect this flow in the liquid phase have been carried out in this laboratory. Flow in the liquid phase was not detected [*Kuzmak* and *Sereda*, 1957]. It therefore appears that the flow takes place in the vapor phase. If the flow does take place in the vapor phase, a possible reason for the discrepancy between the observed and calculated rates may be a discrepancy between the true vapor pressure gradient within the pores of the material and the vapor pressure gradient used in making the calculations.

This paper describes an experiment in which the temperature distribution in a model of a porous material was measured. From these measurements, temperature gradients were calculated. The corresponding vapor pressure gradients can also be calculated.

Experimental—The following considerations lead to the design of the model. The moisture in wet sand is presumed to be distributed as thin films on the surfaces of the solid particles, but mainly concentrated in wedge-shaped rings around the points of contact between adjacent particles. Referring to Figure 1, vapor flow may be assumed to occur under a temperature gradient by a process of evaporation in region A, diffusion across the air space, and condensation in region B. In an open system this does not result in a moisture gradient if equal suctions are maintained at the open boundaries. Assuming that the resistance to liquid flow from one side of the water ring A′A to the other is negligible, then the quantity that determines the rate of moisture flow under a temperature gradient is the average vapor pressure gradient in the pore space AB.

One method by which the vapor-pressure gradients in the pore space may be investigated is to determine the temperature distribution in the pore space and on its bounding surfaces since the temperature conditions are the cause of the vapor pressure conditions. A rigorous mathematical approach to the determination of the temperature distribution in such a system appears to be intractable unless simplifying approximations are made. The alternative is to construct an enlarged model of the grain-pore system, impose a temperature gradient upon the model, and measure temperatures at selected locations within the system after establishing thermal equilibrium.

The two extreme packing arrangements of a granular material composed of uniform spherical particles are the open and close packing arrangements. The open packing arrangement, wherein the spheres form a cubic lattice as in Figure 2, was selected for reasons of simplicity. By symmetry the planes through the horizontal full lines perpendicular to the plane of the figure, are all isothermal planes. Similarly the orthogonal planes through the vertical dashed lines are heat flow planes. Thus the temperature distribution in the

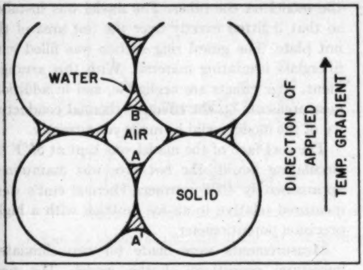

FIG. 1 – Representation of moisture distribution within the pore spaces of a granular material

space enclosed by the heavy full lines is representative of the distribution throughout the material. The model which was constructed is shown in Figure 3, and consisted of four marble hemispheres six inches in diameter, contained in a box, the top and bottom of which was $\frac{3}{8}$ inch aluminum and edges $\frac{1}{8}$ inch lucite.

The temperature distribution in such a system under a temperature gradient will depend upon the relative thermal conductivities of the three constituents, air, water, and solid, as well as upon the configuration or geometry of the system. Let k_a, k_w, and k_s represent the thermal conductivities of the air, water, and solid respectively. In the model the materials must be selected so that the ratios k_w/k_a and k_s/k_a are similar to the corresponding ratios for an actual sand.

The following thermal conductivity values apply to a wet sand of high quartz content at 20°C:

k_s = thermal conductivity of quartz = 20.7 $\times 10^{-3}$ cal/cm sec°C

k_w = thermal conductivity of water = 1.42 $\times 10^{-3}$ cal/cm sec°C

k_a = effective thermal conductivity of saturated air [after *Krischer*, 1941] = 0.238 $\times 10^{-3}$ cal/cm sec°C

The value for k_a is not the thermal conductivity of dry air alone, which at this temperature is 0.0615 $\times 10^{-3}$ cal/cm sec°C, but includes a term which accounts for the latent heat carried by evaporation, diffusion, and condensation of water vapor. By simulating this value of k_a in the model, the effect of evaporation and condensation upon the temperature distribution is taken into account. Thus for a wet sand, $k_w/k_a = 5.96$, and $k_s/k_a = 87.0$.

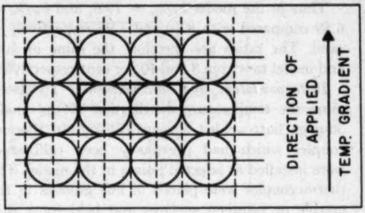

FIG. 2 – Two-dimensional representation of the open-packing arrangement simulated in the model

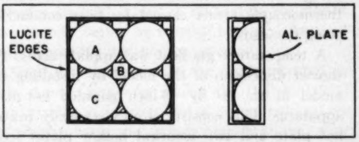

FIG. 3 – The model; A, marble hemispheres; B, silica aerogel; C, bitumen rings

The following materials were used in the model:

(1) Marble was used to represent the solid particles in the model. The four six-inch diameter white marble hemispheres were made spherical to better than $\frac{1}{64}$ inch. Two 8- by 8- by 1-inch slabs of marble were obtained from the same source, so that the thermal conductivity of the marble could be measured in an 8- by 8-inch guarded hot plate apparatus.

(2) Bitumen was chosen to represent the water in the model, since it could be shaped, without too much difficulty, into the wedge-shaped water rings around the points of contact between the solid hemispheres. The thin water films on the particle surfaces were not simulated in the model, since it was thought that they would play a minor role in determining the temperature distribution.

(3) Silica aerogel, rather than air itself, was selected to represent the air in the model to prevent convection.

The following thermal conductivity values apply to the sand model constituents at 20°C:

k_s = thermal conductivity of marble = 4.60 $\times 10^{-3}$ cal/cm sec°C

k_w = thermal conductivity of bitumen = 0.379 $\times 10^{-3}$ cal/cm sec°C

k_a = thermal conductivity of silica aerogel = 0.0576 $\times 10^{-3}$ cal/cm sec°C

Thus in the model $k_s/k_a = 79.6$, and $k_w/k_a = 6.59$ compared with 87.0 and 5.96 respectively in sand. The ratios are therefore the same in sand and model to within 8 and 10 per cent respectively.

Instrumentation and measurements—To determine the temperature distribution in the model 36-gage butt-welded chromel-constantan thermocouples which had previously been calibrated, were installed at selected points in the model. The thermocouples were placed in fine grooves in the marble or bitumen surfaces and held by a thin coat of adhesive. The thermocouples' leads were brought out along the lines of latitude of the hemispheres. Since the lines of latitude are close to being isothermal lines, this method minimizes thermocouple errors caused by heat conduction along the leads.

A temperature gradient was applied across the shorter dimension of the model by installing the model in an 18- by 18-inch guarded hot-plate apparatus. This consists of an electrically heated hot plate and two identical hollow plates (cold plates) cooled by the circulation of constant temperature liquid, and situated one on each side of the hot plate. All plates are 18 inches square. The hot plate is made in two sections, a central 12-inch square test area and an outer 3-inch wide guard ring, which are heated independently and maintained at the same temperature to minimize edge effects. A slab of 18- by 18- by 1-inch fiberboard was placed on one side of the hot plate and the model on the other. The model was installed so that it fitted exactly over the test area of the hot plate. The guard ring section was filled with fiberglass insulating material. With this arrangement, edge effects are negligible, and in addition, measurements on the effective thermal conductivity of the model could be made concurrently.

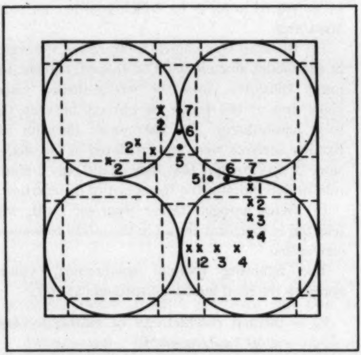

FIG. 4 – Diagram of model showing location of thermocouples; x, on marble surface; ●, on bitumen surface; 1, 2, 3, 4, θ = 30, 45, 60, 75° respectively (on spheres); 5, 6, 7, θ = 30, 60, and 90° respectively (on rings); θ = angle of latitude

The cool face of the model was kept at 55°F by circulating liquid; the hot face was maintained approximately 40°F warmer. Thermal emf's were measured relative to an ice junction with a high-precision potentiometer.

Measurements were made for two simulated 'moisture' conditions of the model. The first represented an air-dry condition, that is, water films on the particle surfaces, but no water rings at the points of contact. Thus for this condition in the model, the entire space not occupied by the marble hemispheres was filled with silica aerogel. The locations of the thermocouples are shown in Figure 4. Measured temperatures at similar positions on the two hemispheres agreed to within one per cent. At the completion of this test, the model was removed from the apparatus, re-installed and the test repeated. Reproducibility was within two per cent.

The second 'moisture' condition simulated in the model represented a moisture content of 26.6 pct by volume of saturation moisture content, or a moisture content of 12.7 pct by volume assuming the porosity to be 0.4764 (actual measured porosity of the model = 0.4711). This 'moisture content' corresponded to bitumen 'water' rings of two-inch radius at the points of contact between hemispheres. No attempt was made to simulate the meniscus curvature of the 'water' rings. The locations of the thermocouples are shown in Figure 4.

Results—From the emf developed by each thermocouple, a temperature corresponding to each thermocouple position was determined. Taking into account the symmetry, the temperature differences between mirror image points separated by the air gap were calculated. The average temperature gradient between any two such points was assumed to be that obtained by dividing the temperature difference by the distance between the points.

The temperature difference between the two isothermal metal plates divided by the distance between them is equal to the over-all gradient. For the different angles of latitude the ratio F of the gradient between mirror image points on the surface of the solid to the over-all gradient was calculated. These are shown in Figure 5a for the

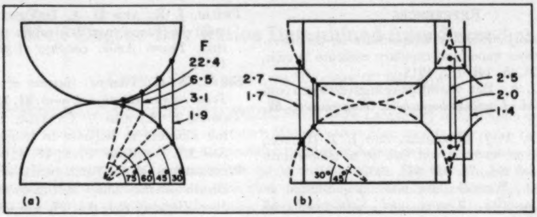

FIG. 5 – Values of the ratio F for (a) the system solid and air; (b) the system solid, air, and water

system solid and air, and in Figure 5b for the system solid, air, and water.

Since the magnitude of F changes with angle of latitude, an average value of F is desirable. Figure 5a shows the value of the factor F at angles of latitude of $\theta = 30$, 45, 60, and 75° for the system solid and air. The value of F at $\theta = 15°$ was interpolated from a graph of F vs θ ($F = 1$ at $\theta = 0$). The average value of F, between $\theta = 7.5°$ and 82.5°, taking account of the slope of spherical surface, and assuming linear flow of heat in the pore spaces, was calculated as

$$\overline{F} = \frac{\frac{\pi}{12}\sum_{i=1}^{5} F_i \cos\theta_i \sin\theta_i}{\int_{\pi/24}^{11\pi/24} \cos\theta \sin\theta \, d\theta} = 6.02$$

where $\theta_i = 15$, 30, 45, 60, and 75°, and F_i are the corresponding values of F. No suitable averaging method could be found for determining $\overline{F}$ for the system solid, air, and water.

Discussion—For the system solid and air, the average value of F is 6, that is, the average temperature gradient across the pore space is six times the over-all gradient. It follows therefore that approximately this same ratio exists between the respective vapor pressure gradients. For the system solid, air, and water, the average value of F was not calculated, but a consideration of the values of F in Figure 5b indicates that the average would be less than six. As the moisture content of the system decreases from 26 pct toward zero, the average value of F will approach 6.

It is therefore proposed that the mechanism of movement involves multiple vapor diffusion and liquid flow steps in series. The resistance to flow in the liquid phase is considered negligible (at least at high relative humidities) so that the rate of moisture transfer is determined by the rate of vapor diffusion. Consequently, if the correct vapor pressure gradient is used in calculating the rate of flow, much better agreement between observed and calculated rates may be expected.

After the completion of the work reported in this paper, a paper by *Philip* and *DeVries* [1957] was brought to the attention of the present authors in which, from theoretical considerations, they arrived at the same general conclusion as reported in this paper regarding the mechanism of moisture flow through a porous material subjected to a temperature gradient. Theoretical values of $\overline{F}$ (denoted by ζ) were tabulated for different porosities and moisture contents. These values ranged between 1.3 and 3.2. If the Philip and DeVries method [*DeVries*, 1952] for calculating $\overline{F}$ is used, a value of 2.04 is obtained for the air-dry condition of the model, compared with the above measured value of 6.02. The Maxwell-Burger-Eucken theory, on which the Philip and DeVries method is based, assumes that the distances between particles are large compared with the particle size. Now, if one makes the approximation that the granular material may be represented by an air layer and a solid layer in series, $\overline{F}$ is found to be 2.09 for the porosity and conductivity ratio used in the model. The fact that the value obtained making this very rough approximation is similar to that calculated by the Philip and DeVries method indicates that the Maxwell-Burger-Eucken theory, because of the assumption concerning the distances between particles, is not applicable to most granular materials.

Acknowledgments—The authors gratefully acknowledge discussions with P. J. Sereda and D. G. Stephenson concerning the design and construction of the model.

Snow-Melt Degree-Day Ratios Determined from Snow-Lab Data

LEONARD L. WEISS AND WALTER T. WILSON

Abstract—Observations made at the Central Sierra Snow Laboratory in California and the Upper Columbia Snow Laboratory in western Montana have been used to determine the ratio of the amount of snow melt to the accumulated number of degree days or degree hours above selected base temperatures during the late spring melting season. The use of degree days was found to give smaller errors of estimation than degree hours, and a base temperature of 32°F gave smaller errors of estimation than other bases tried. The ratio was found to be smaller for greater forest cover and to increase during the melting season. No relation was found between the ratio and average wind, humidity, or cloudiness. These, of course, have important physical effects on the heat supply to a snow cover, but variations in their effect could be obscured by the fact that they were averaged over weekly or longer periods, and some of their effect may be included in the time-of-year parameter.

Introduction—The average air temperature during a melting period can be considered an index of the integrated effect of radiation, and sensible heat exchange. If it is assumed that negligible snow melting will occur when the air temperature is below some certain value, this value can be chosen as a base temperature and the difference between the observed air temperature and the base can be used as an index of the heat available for melting. When hourly temperatures are used and differences summed for the melting period, the total is called degree hours for the period. When mean daily temperatures are used the summed differences are called degree days. In this study, mean daily temperature is the sum of the recorded daily maximum and minimum divided by two.

It is the purpose of this paper to report the empirical relations between the accumulated degree days (or degree hours) and the concomitant snow melt, as determined from the data in the *Hydrometeorological Logs* of the Cooperative Snow Investigations of the Corps of Engineers and the Weather Bureau. These logs constitute a unique set of carefully observed integrated data from which to determine such relations. Reference to these logs may be made for heights of instruments, descriptions of snow and temperature sites, occurrence of snow cover at time of temperature observations, etc. Data for selected stations in the Central Sierra Snow Laboratory (CSSL) in California for the snow melting season (April–June) of the years 1947–52 and in the Upper Columbia Snow Laboratory (UCSL) in western Montana for the snow melting season (April–June) of the years 1947–50 were chosen. The selection was made to provide examples for different station-site conditions of exposure and forest cover, with consistent and uniform coverage of data. Temperatures at stations 1 and 1b were recorded at four feet above the snow or ground surface; at site stations this height varied considerably, but averaged about ten feet above the ground.

Daily changes in water equivalent of the snow pack during the melting season frequently amount to about an inch. Single point observations of snow-pack water equivalent may have sampling and instrumental errors of about an inch (standard error). These errors obscure the empirical relationship when daily changes are used. Because of this, selected periods used were usually weekly, occasionally biweekly or monthly, in order to permit the increment of change in snow-pack water equivalent to greatly exceed its observational error, and the error inherent in making corrections for rainfall.

Method of analysis of the data—The analysis consisted of plotting the change in water equivalent of the snow pack (adjusted for any rainfall during the period) versus the degree days (or degree hours) for the same time period on arithmetic cross-section paper and fitting an estimated line of best fit to the points by inspection. The slope of this line is called the degree-day (or degree-hour) ratio, and represents the inches of melt (water equivalent) per degree day (or degree hour).

The ratios were determined using different base temperatures. The magnitude of the standard error of estimate of snow melt divided by the mean of the snow-melt values for all the periods was used as a basis of comparison of the ratios. About twenty periods were available for the determination of each ratio. Tests indicated that the relations were not improved by including the effect of negative degree hours. There were too few negative degree days for an adequate test.

To illustrate the relation of the ratio magnitude

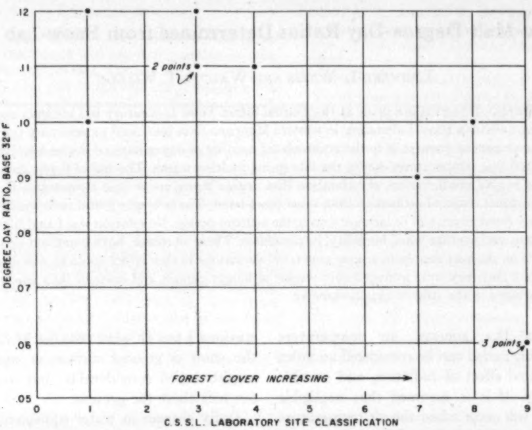

FIG. 1 - Illustrating the decrease of degree-day ratio with increase of forest cover

FIG. 2 - Illustrating the decrease of degree-day ratio with increase of forest cover

to the amount of forest cover, the ratios for a base temperature of 32°F were plotted versus the laboratory-site classification number and are shown in Figures 1 and 2. The site classifications are given in Tables 1 and 2 and represent a measure of forest cover. Ratios were plotted versus average dew point, average cloudiness, and average wind speed for the period, but no relationship was detected.

To determine whether the ratio varied with the time of year within the melting season, the ratio values for each melting period (usually about seven days) were assigned the date of the mid-point in the period. Only those periods were used where the incremental change was two inches or more. The season was then divided into ten-day intervals starting April 1. All the ratios for a given station whose mid-date fell within the ten-day interval were averaged. These average ratios were then plotted versus time of year and fitted by inspection with straight lines. Examples are shown in Figures 3 and 4.

Results of the analysis—The ratios determined by using different base temperatures are compared in Tables 1–5. The use of a base temperature of 32°F is seen to give the smallest average standard error in per cent of the mean. Over the range of station elevations in CSSL the difference in the ratios determined from temperature observations at the melting site or at another station are too small to be of practical consequence. However, in UCSL where the differences in station elevation can exceed a thousand feet, a temperature adjustment may be necessary when the temperatures are observed at a station other than the melting site. For this adjustment an average decrease of temper-

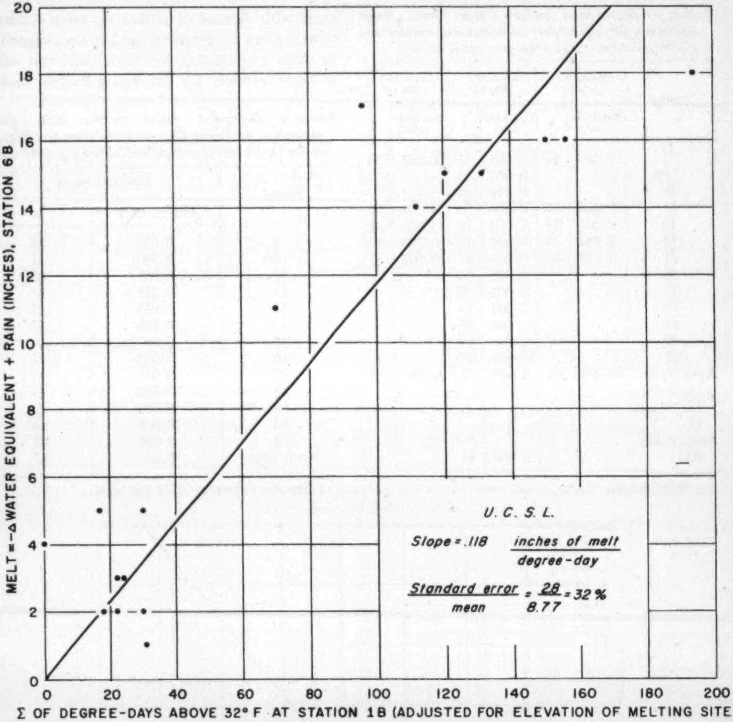

FIG. 6 – Example of determination of degree-day ratio

in these laboratories, and have used it to adjust the daily mean temperatures at station 1b for elevation of the melting site. The ratios resulting from use of these adjustments are included in Table 2.

It was expected that total melt would correlate better with degree-hour summations than with degree-day summations. However, this was found on the average not to be the case. That this result was not solely due to using long periods was supported by a comparison of the scatter diagrams of degree days above 32°F and degree hours above 32°F versus the daily streamflow at Castle Creek (CSSL). The scatter was large but was less for degree days than for degree hours.

Degree-day ratio determinations using the daily maximum rather than the daily mean temperature were made for base temperatures of 35, 37, 40, and 45°F in CSSL. The results are shown in Table 4. Forty degrees was slightly better than the other bases, but the average standard error in per cent of the mean was about 50 pct greater than that for the daily mean temperature method. Degree-day ratios for base 40 and daily maximum temperature in UCSL are shown in Table 6.

A decrease of the degree-day ratio was expected with increase in forest cover. Figures 1 and 2 show the ratios in terms of forest cover as indicated by the laboratory-site classifications. These classifications are somewhat arbitrary, do not increase in linear fashion and are different for the two laboratories. But the figures indicate the important

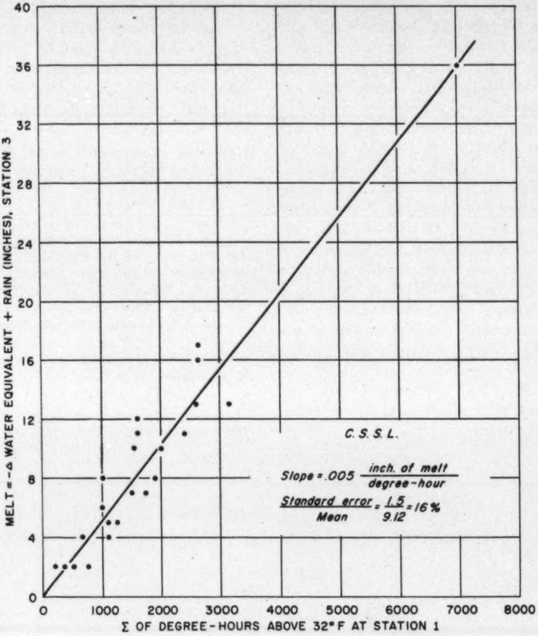

FIG. 7 – Example of determination of degree-hour ratio

influence of forest cover in decreasing the melting rate. For stations in forest the season-mean degree-day ratio of about 0.06 is indicated; for open sites about 0.12 and for intermediate locations about 0.09. In Figure 2 (UCSL) the ratios used were those adjusted for elevation difference between the temperature site and the melting site.

A variation of ratio magnitude with time of year within the melting season was found such that the mean values as given in the tables apply to early May and vary from 0.7 of the mean value for early April to 1.3 times the mean value for early June.

Discussion—The points which determine the ratio show considerably greater scatter for UCSL stations than for CSSL stations. This is probably because CSSL has less variability of air masses, and less advective change. At UCSL the topography is more rugged with air occasionally spilling over the continental divide from the east giving greater variability in temperature and humidity. Also there is greater probability of change in albedo of the snow at UCSL because of intermittent snow late in the season, with alternations of new and old snow being exposed to the sun.

It has been observed that the total storage of liquid water in a snow pack seldom exceeds five per cent of the water equivalent of the pack. Changes, during the melting periods studied, in the small liquid component of the water equivalent of the pack are believed to be negligibly small compared with the change in total water equivalent over the same periods.

During the progress of the melting season, the average dew point and average incident radiation for the melting periods gradually increases, the the average cloudiness decreases. Even though no relations between the ratios and these individual parameters were detected, their combined influence may be included in the time-of-year parameter which does show a relationship.

The degree-day ratios give estimates for (generally) weekly periods with standard error of less than 30 pct of the mean as indicated by the dependent data of the scatter diagrams. The correlations were all above 0.80. For shorter time intervals, poorer correlations would be expected.

Sample scatter diagrams showing determination of degree-day ratios are shown in Figure 5 for CSSL and in Figure 6 for UCSL. One showing degree-hour ratio is shown in Figure 7 for CSSL. The rain adjustments added to the change in water equivalent were measured at Stations 1 or 1b.

Conclusions—The following conclusions are drawn. (1) The use of degree-day summations based on daily mean temperature gave smaller errors of estimate of concomitant snow melt than degree-hour summations; and both were superior to the use of summations based on daily maximum temperature.

(2) The use of a temperature base of 32°F gave the smallest standard error of estimate in per cent of the mean.

(3) The season-mean degree-day ratio for sites within forest was 0.06 inches snow melt per degree day; for sites in the open 0.12, and for intermediate sites about 0.09. This mean value applies to early May. For early April the values were 0.04, 0.08, and 0.06 respectively. For early June they were 0.08, 0.16, and 0.12 respectively.

(4) The degree-day ratio was as satisfactory for estimating snow melt in open and windy locations as at forest sites.

Two-Dimensional Gravity Drainage Profiles

B. J. HOLLINGSWORTH AND H. I. MEYER

Abstract—This paper concerns some studies made on the shape of the fluid-fluid interface of a liquid which is draining by gravity from a saturated porous medium. The first part is a review of the classical potential theory solution by *Hamel* and *Gunther* [1935]. This solution is then put into a form amenable to solution by a digital computer and some discussion of the numerical methods employed is given. The results of a series of numerical solutions are used to define an area function which is employed along with the mass balance concept and the idea of a succession of steady states to derive an expression for transient drainage from a two dimensional saturated medium. This transient solution is compared with the actual drainage rate from a Hele-Shaw analog system.

Introduction—This paper concerns some studies made in our laboratory on the shape of the free surface, that is, the fluid-fluid interface, of a liquid which is draining by gravity from a saturated porous medium. Both analytic and experimental results are discussed. Our studies were confined to two dimensional flow problems. The classical physical analogy is that of seepage through a dam with vertical faces. References to previous work on this problem are given by *Muskat* [1946] whose Chapter 6 on gravity-flow systems is probably the most pertinent single reference.

The first part of this paper is a review of the classical potential theory solution by *Hamel* and *Gunther* [1935]. This solution is then put into a form amenable to solution by a digital computer and some discussion of the numerical methods employed is given. The results of a series of numerical solutions are used to define an area function which is employed along with the mass balance concept and the idea of a succession of steady states to derive an expression for transient drainage from a two dimensional saturated medium. This transient solution is compared with the actual drainage rate from a Hele-Shaw analog system.

Description of the problem—We are concerned with the system sketched in Figure 1, using the notation of *Muskat* [1946, p. 303]. Only the case where the downstream liquid level is zero is considered. Analytical solutions will give the coordinates of the free surface and the dimensions h and L in terms of a system parameter $\bar{k}$ and a mapping parameter b. The system parameter is defined by the equation in the dimension of length

$$k = k\gamma g/\mu \tag{1}$$

where

γ is fluid density
μ is dynamic viscosity
g is acceleration of gravity
k is the permeability defined by the Darcy equation

$$v = -k(\gamma/\mu)\,\mathrm{grad}\,\phi \tag{2}$$

in which v is the fluid velocity vector, and ϕ is the potential function, $gZ + (p - p_0)/\rho$, p being pressure. These are familiar expressions. The mapping parameter b is defined in the next section.

Analytical solution—To review the solution of *Hamel* and *Gunther* [1935], the hodograph of Figure 1 is shown in Figure 2, and β makes its appearance. This is now mapped to what Hamel calls the $\underline{q}$ plane by the mapping function $q = i(u - iv)/k$ to obtain Figure 3. This may finally be transformed to a single straight line by the mapping function

$$\lambda = [\Theta(q) - 1]/\Theta(q) \tag{3}$$

where $\Theta(q) = K^2$ is the modular elliptic function of modulus K defined by the relations

$$\Theta(0) = 1, \quad \Theta(1) = \infty$$
$$\Theta(i^{\infty}) = \Theta(1 + i^{\infty}) = 0$$

The original boundary conditions of the problem, which may be stated in terms of a complex velocity potential $\phi(Z)$ are not easily carried through these transformations but an intermediate potential function defined by the relation

$$\theta - i\tau = i \log\,[-d^2\phi/dZ^2] \tag{4}$$

has the boundary values of its real part specified in each transformation. The values of θ in the final transformation are shown in Figure 4 [Muskat, 1946, Fig. 101]. Since values of θ are known along the whole real axis and the upper half plane represents the flow region, this last transformation formally solves the problem. The value of $\theta - i\tau$ in the upper half plane is given by

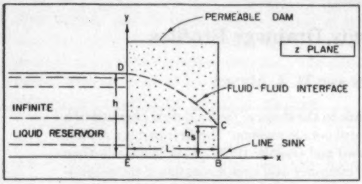

FIG. 1 – Sketch of the system

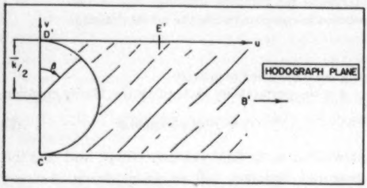

FIG. 2 – Hodograph of Figure 1

$$\theta - i\tau = i\tau_0 + \frac{1}{\Pi i}\int_{-\infty}^{+\infty} \frac{\theta(\epsilon)(\lambda\epsilon + 1)\,d\epsilon}{(\epsilon - \lambda)(1 + \epsilon^2)}$$

where τ_0 is an arbitrary constant [*Muskat*, 1946, p. 308.]

Note that there is only one unspecified parameter in Figure 4, namely, the real coordinate b of the point E'''. Therefore it should be possible to let b vary between the limits 1 and $+\infty$ to determine solutions for all two dimensional problems similar to that shown in Figure 1 in which the ratio L/h lies between 0 and $+\infty$. The subsequent section on ***Numerical evaluation*** shows the difficulty of applying this theory.

Integral equation solutions—Using the identity $dZ = d[\phi(Z)]/\phi''(Z)$ (primes indicate differentiation), we have

$$Z = -\int \frac{d(u + iv)}{\phi''(Z)} = \int e^{\tau + i\theta}\, d(u + iv) \quad (5)$$

having used the definition of τ and θ in (4) and the definition of the complex potential function. Since θ assumes constant values along segments of the real axis in Figure 4, (5) may be integrated along this line which is the free surface in the physical plane to give pertinent expressions. For example, integrating from E to B, where $\theta = 0$ gives an expression for the length L measured through the dam

$$L = \int_{u(E)}^{u(B)} e^{\tau} du \quad (6)$$

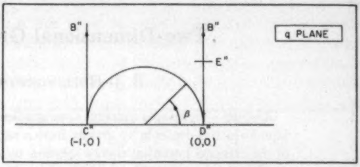

FIG. 3 – Mapping in the q plane

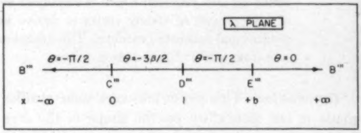

FIG. 4 – Final transformation of θ values

Similarly

$$h = \int_{u(E)}^{0} e^{\tau} du \quad (7)$$

and

$$h_s = \int_{u(B)}^{0} e^{\tau}\, du = -\int_{\infty}^{0} e^{\tau}\, du \quad (8)$$

The coordinates of the free surface involve the parameter β

$$x - L + i(y - h_s) = (k/2)\int_{\Pi}^{\beta} \exp\,(\tau - i\beta/2)\, d\beta \quad (9)$$

Eqs. (6) to (9) are deceptively simple since the functional relationships between the variables are complicated. The following identities and definitions may be used to derive integral expressions amenable to machine solution.

Let $f(K^2)$ be the inverse of the modular elliptic function such that if $\Theta(q) = K^2$, then $iq = -f(K^2)$.

This inverse function is tabulated by *Hayashi* [1930] to ten decimal places. It is closely approximated by the expression

$$iq \simeq \frac{1}{\Pi}\left(\ln \frac{K^2}{16} + \frac{K^2}{2} + \frac{13K^4}{64} + 0.889893\right) K^6 + 0.1958056\, K^8$$

whenever $K^2 \leq \frac{1}{2}$ and by $iq = 1/ - f(1 - k^2)$ whenever $\frac{1}{2} < K^2 \leq 1$. From the geometry of the mapping

$$\left.\begin{aligned}\tan \beta/2 &= f(\lambda)\\ \sin \beta/2 &= f(\lambda)/[1+f^2(\lambda)]^{\frac{1}{2}}\\ \cos \beta/2 &= 1/[1+f^2(\lambda)]^{\frac{1}{2}}\end{aligned}\right\} \qquad (10)$$

$$d\beta = 2d\, f(\lambda)/[1+f^2(\lambda)]$$

Except on the circular arc of the q-plane we have

$$dv = 0 \qquad (11)$$

Relations (10) and (11) allow us to write (6) to (8) in terms of a single variable λ.

$$L = \bar{k} \int_b^\infty \left[\frac{\lambda - 1}{\lambda(\lambda - b)}\right]^{\frac{1}{2}} e^\alpha \, df(1/\lambda) \qquad (12)$$

$$h_s = -\bar{k} \int_{-\infty}^0 \left[\frac{1 - \lambda}{\lambda(\lambda - b)}\right]^{\frac{1}{2}} e^\alpha \, df(1/1 - \lambda) \qquad (13)$$

$$x - L = \bar{k} \int_0^{\lambda \le 1} \left[\frac{\lambda - 1}{\lambda(\lambda - b)}\right]^{\frac{1}{2}} e^\alpha \frac{df(\lambda)}{[1 + f^2(\lambda)]^{\frac{3}{2}}} \qquad (14)$$

$$y - h = -k \int^{\lambda \le 1} \left[\frac{\lambda - 1}{\lambda(\lambda - b)}\right]^{\frac{1}{2}} e^\alpha \frac{f(\lambda)\, df(\lambda)}{[1 + f^2(\lambda)]^{\frac{3}{2}}} \qquad (15)$$

where

$$\alpha(\lambda) = -\frac{3}{\Pi} \int_0^1 \frac{\tan^{-1} f(t)}{t - \lambda}\, dt$$

These equations are in a convenient form for evaluation by a digital computer.

Numerical evaluation of the integrals—Hamel and *Gunther* [1935] give a table of α in the range, $-20 \le \lambda \le 20$. Since this table was too abbreviated for our work, the integral was evaluated as shown below. For $0 < \lambda < 1$

$$\begin{aligned}\alpha &= -\frac{3}{\Pi} \int_0^1 \frac{\tan^{-1} f(t)\, dt}{t - \lambda}\\ &= -\frac{3}{\Pi}\left[\int_0^1 \frac{\tan^{-1} f(t) - \tan^{-1} f(\lambda)}{t - \lambda}\right.\\ &\qquad\qquad \left. + \tan^{-1} f(\lambda) \left\{\ln \frac{1-\lambda}{\lambda}\right\}\right]\\ &\simeq -\frac{3}{\Pi}\left[\sum_{i=1}^{8} \cdot R_i \frac{\tan^{-1} f(\mu_i + \frac{1}{2}) - \tan^{-1} f(\lambda)}{u + \frac{1}{2} - \lambda}\right.\\ &\qquad\qquad \left. + \tan^{-1} f(\lambda) \left\{\ln \frac{1-\lambda}{\lambda}\right\}\right]\end{aligned}$$

in which the R_i and μ_i are respectively the weight factors and point coordinates defined by the Gauss quadrature method using eight points [*Scarborough*, 1950, sec. 49].

When $|\mu_i + \frac{1}{2} - \lambda| \le 0.005$, the factor

$$\frac{\tan^{-1} f(\mu_i + \frac{1}{2}) - \tan^{-1} f(\lambda)}{\mu_i + \frac{1}{2} - \lambda}$$

is replaced by its limit as $|\mu_i + \frac{1}{2} - \lambda|$ approaches zero

$$\left[\frac{df(\lambda)}{d\lambda}\right] \Big/ [1 + f(\lambda)]$$

For λ outside the interval (0, 1)

$$\alpha(\lambda) \simeq -\frac{3}{\Pi} \sum_{i=1}^{8} R_i \frac{\tan^{-1} f(\mu_i + \frac{1}{2})}{\mu_i + \frac{1}{2} - \lambda}$$

Eq. (12) and (13) have such critical singularities that the Gauss quadrature method may not be directly applied. A brute-force method of series expansion was used as indicated below

$$\begin{aligned}\frac{L}{\bar{k}} &= \int_l^\infty F(\lambda) = \int_b^{b+\epsilon} + \int_{b+\epsilon}^\infty\\ &= \int_{b+\epsilon/10}^{b+\epsilon} + \int_{b+\epsilon/100}^{b+\epsilon/10} + \int_{b+\epsilon/1000}^{b+\epsilon/100} + \cdots\\ &\qquad + \int_{b+\epsilon}^{2(b+\epsilon)} + \int_{2(b+\epsilon)}^{4(b+\epsilon)} + \int_{4(b+\epsilon)}^{16(b+\epsilon)} + \cdots \qquad (12')\end{aligned}$$

$$\begin{aligned}\frac{h_s}{\bar{k}} &= \int_{-\infty}^0 G(\lambda) = \int_{-2}^0 + \int_{-\infty}^{-2}\\ &= \int_{-2}^{-\frac{1}{2}} + \int_{-\frac{1}{2}}^{-\frac{1}{4}} + \int_{-\frac{1}{4}}^{-\frac{1}{16}} + \cdots\\ &\qquad + \int_{-4}^{-2} + \int_{-16}^{-4} + \int_{-256}^{-16} + \cdots \qquad (13')\end{aligned}$$

The integral terms in each series expansion were evaluated by the four point Gauss quadrature method until their contributions became negligible.

Twelve sets of coordinate points x_i, y_i were computed by (14) and (15) along the interface for each value of b using

$$\frac{x_i - L}{\bar{k}} = \int_0^{\lambda_i} H(\lambda), \qquad \frac{y_i - h}{\bar{k}} = \int_0^{\lambda_i} I(\lambda)$$

The values chosen for λ_i were $\lambda_1 = 0.5$, $\lambda_2 = 0.9$, 0.96, 0.975, 0.988, 0.994, 0.997, 0.9985, 0.9993, 0.9999, and $\lambda_{12} = 1.0$. Obviously x_{12} should equal zero, this was used to check the numerical integration.

As mentioned in *Analytical solutions*, it should be possible, by selecting values of b between the limits of 1.0 and ∞ to obtain solutions for any problems of the type sketched in Figure 1. *Muskat* [1946, p. 314] presents four solutions from b = 1.2 to 10.0 which show an encouraging variation. However as we found on evaluating the integrals that for thin dams ($L < h/3$) the values of b must

be tremendously large while for thick dams ($L > 1.5h$) the values of b are only slightly larger than 1.0. We did the best we could with the computer we had and chose the following values for b; 1.0000001, 1.0001, 1.001, 1.1, 1.2, 2, 5, 10, 20, 80, 325, 1500, 6000, 60000, 10^9. (These calculations were made on an IBM CPC using floating-point arithmetic, eight significant figures, and an exponent range 10^{-50} to 10^{+50}. It is doubtful that 'double precision' arithmetic could significantly extend our table.) The results of these calculations are presented in Table 1.

The area function—We define a function $A^*(L^*)$ which is the area of the saturated cross section of a dam of length L^* when the upstream liquid height h equals unity. This function will be useful later. These areas were computed by elementary methods and the function is tabulated in Table 2.

Transient-flow solution—In studying a succession of steady states, consider the sketch shown in Figure 5. Liquid is allowed to drain from a semi-infinite porous slab. At some time t during the drainage process the free surface is given by surface 1, the slab for all $x > L$ is still fully saturated. At a later time $t + \Delta t$, surface 2 obtains and the slab is saturated for $x > L + \Delta L$. We know from experiment that this is an accurate picture of the drainage process. The distance L(or $L + \Delta L$) is defined as the effective drainage distance.

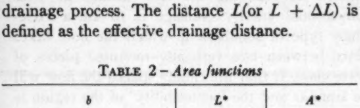

FIG. 5 – Sketch showing succession of steady states

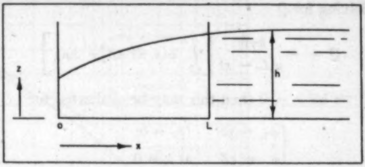

FIG. 6 – Sketch for determining integral expression for flow rate

Now we approximate this transient process by a succession of steady state solutions. The hypothesis is: the rate of flow, Q, at time t is equal to the flow rate through a dam of thickness $L(t)$ of the same permeability with fluid head at the inflow face equal to h. If W is the width of the outflow face and s is the medium porosity then obviously

$$Q \text{ (flow rate)} = Ws\, dA(L)/dt \qquad (16)$$

if A is the area of the saturated area from $0 < x < L$. This may be expressed in terms of the area function $A\ (L^*)$, for if $L^* = L/h$ then $A = A^* \cdot h^2$. We need another expression for Q.

As *Hubbert* [1940] pointed out, the liquid-potential function, $\phi = gZ + (p - p_0)/\rho$, is defined not only within the saturated region but in all space. Of particular interest is its definition in the drained region above the free surface, $\phi = gZ - p_0/\rho$. The flow rate is evidently given by the integral expression (see Fig. 6)

$$Q = -W \int_0^h v_x(x, Z)\, dZ \qquad (17)$$

in which v_x is the x component of the velocity vector ($v_x \equiv 0$ above the free surface).

$$v_x = -\frac{k\gamma}{\mu}\frac{\partial \phi}{\partial x}$$

or equivalently

$$\phi(x, Z) = \frac{u}{k\gamma}\int_x^L v_x(\zeta, Z)\, d\zeta + \phi_L \qquad (18)$$

where ϕ_L is the (constant) potential at the inflow face. Set

$$\begin{aligned} W \int_0^h \phi(x, Z)\, dZ \\ &= W \int_0^h \left\{ \frac{\mu}{k\gamma} \int_x^L v_x(\zeta, Z)\, d\zeta + \phi_L \right\} dZ \\ &= -\frac{\mu}{k\gamma}\, Q(L - x) + Wh\phi_L \end{aligned}$$

Solving for Q

$$Q = -\frac{k\gamma W}{\mu(L - x)}\left[\int_0^h \phi(x, Z)\, dZ - h\phi_L\right]$$

If we let $x = 0$ then this may be evaluated for

$$\begin{cases}\phi_L = gh & (p_0 = 0)\\ \phi = gZ & \text{at } x = 0\end{cases}$$

so that

$$Q = +\frac{h^2 k\gamma W g}{2\mu L} \tag{19}$$

The corresponding equation for drainage rate from a radial system was previously given in an article on water coning [*Meyer* and *Garder*, 1956].

This is the *Dupuit* [1863] equation for gravity drainage rate. It has been derived by valid methods rather than from the incorrect assumptions that he used. (This must certainly be one of few instances where the correct formula was derived from incorrect postulates.) *Muskat* [1946, p. 314] used both this formula and a conformal mapping solution to compute the flow rate through a dam and found good agreement.

TABLE 3 – *Pertinent dimensions*

Experiment	b	h	h'
1	0.0075	19.4	15.6
2	0.0145	18.3	16.3
3	0.0145	19.8	17.8
4	0.0150	19.9	18.0
6	0.0137	20.6	18.5
7	0.01375	19.4	17.3
8	0.0138	19.5	17.4

To determine the transient drainage equation, we combine (16) and (19)

$$Ws\frac{dA}{dL}\frac{dL}{dt} = \frac{h^2 k\gamma W g}{2\mu L}$$

or

$$\int L\frac{dA}{dL}\, dL = \frac{h^2 k\gamma g}{2\mu s}\, t \tag{20}$$

The area function A^* is closely approximated in the region of Table 2 by the linear equation $A^* = 0.636\ L^* + 0.124$, consequently $A = 0.636\ Lh + 0.124\ h^2$. Substituting this into (20), integrating and using the initial condition $L = t = 0$, we obtain

$$L(t) = 1.254\ [\gamma ghkt/(\mu s)]^{\frac{1}{2}} \tag{21}$$

and

$$Q(t) = 0.399\ Wh[\gamma ghks/(\mu t)]^{\frac{1}{2}} \tag{22}$$

Since the derivation of these equations depends on the assumed validity of the approximation by a succession of steady states we would like to compare values computed from them with experimental data.

Experimental drainage studies—An attractive method of studying the free surface in two-dimensional gravity drainage is to use a Hele-Shaw type of simulator in which the flow takes place between two vertically mounted pieces of plate glass. If they are closely spaced the flow will be laminar and the 'permeability' of the region is given by $k = b^2/3$ where b is half the plate spacing [*Rouse*, 1938, sec. 38]. Using this value for the

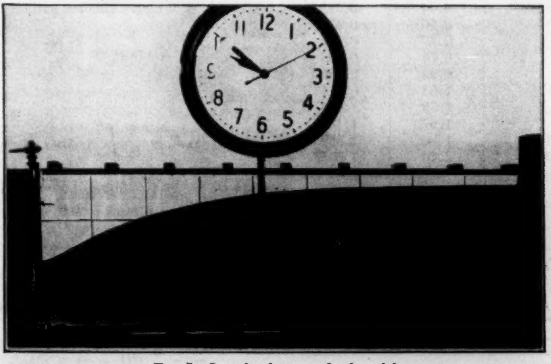

FIG. 7 – Sample photograph of model

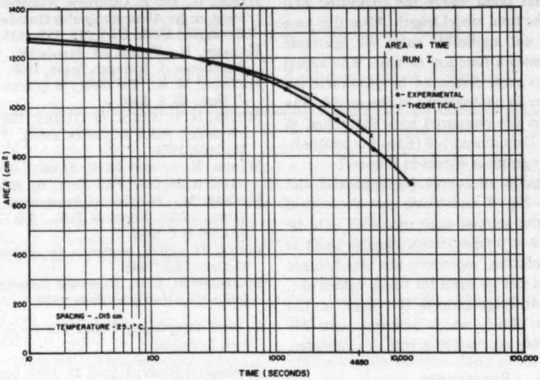

FIG. 8 – Area-time curves for Experiment 1

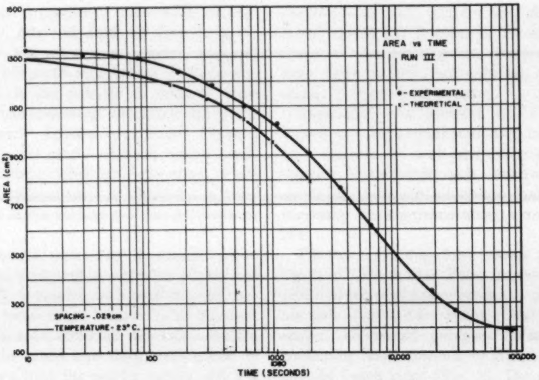

FIG. 9 – Area-time curves for Experiment 3

permeability, (21) and (22) become

$$L(t) = 0.724\, b[\gamma g h t/\mu]^{\frac{1}{3}} \tag{23}$$

$$Q(t) = 0.460\, b^2 h[\gamma g h/\mu t]^{\frac{1}{3}} \tag{24}$$

since $s = 1$, $W = 2b$.

The actual Hele-Shaw apparatus used has been described in a previous paper [*Meyer* and *Searcy*, 1956], for these tests the upstream end of the flow region was sealed and the downstream end was left open. The shape of the free surface was not in good agreement with theory because of capillary effects. Since it is impossible to assign a precise value to L from model photographs we concerned ourselves only with the drainage rate. All studies were made with a fluid (oil) whose specific gravity was 0.8838 and viscosity 1.4857 poise. The pertinent dimensions are given in Table 3. In this table h is the actual fluid height at the start of the experiment, h' includes a capillary correction $h' = h - \sigma/\gamma g h$ where σ is the surface tension of the liquid.

Using b and h' and (23) and (24) the saturated area of the model was computed as a function of time up to that point where the computed $L(t)$ was equal to the total model length. After this time our theory is not applicable since the upstream height h' becomes a function of time. The actual saturated areas were measured by planimetering the shaded area in photographs of the model. The computed areas are compared with the actual in graphs labeled Experiment 1–8 (Exp. 5 is omitted). A sample photograph is shown in Figure 7.

The two families of curves (experimental and computed, see Fig. 8 and 9) do not show good agreement at the start of each run. This is to be expected since $t = 0$ represents a singular point in the analytic solution, moreover the steady-state assumption can not be valid for small values of t. Later in the drainage process the slope of the curves do agree closely which indicates that (24) gives a reasonably accurate flow rate as t increases.

Rate and Depth of Thaw in Arctic Soils

J. V. DREW, J. C. F. TEDROW, R. E. SHANKS, AND J. J. KORANDA

Abstract—Measurements at Point Barrow, Alaska, indicate that rate and depth of thaw in Arctic soils are highly related to soil type. Arctic brown soil thawed earlier in the spring, thawed to a greater depth, and froze earlier in the fall than did the adjacent poorly drained areas. During 1956, arctic brown soil thawed to a maximum depth of 40 inches while the depth of thaw in the nearby tundra soil approximated 18 inches. Diurnal near-surface temperature amplitude was greater in the arctic brown than the adjacent poorly drained areas. The willow-lichen-moss complex was the dominant vegetation with the arctic brown soil, while in the tundra soil, it consisted mainly of *Dupontia-Carex-Eriophorum scheuchzeri*. Other vegetation units in relation to soils are given.

A voluminous literature dealing with permafrost research in North America has included important information on depth of thaw in various mineral and organic soil materials under different kinds of plant cover. Geologists, engineers, and botanists [*Black*, 1950; *Cook*, 1955; *Bliss*, 1956; among many others] have endeavored to relate this information to conditions observed in the soil. Until recently, rate and depth of thaw in arctic soils, however, had not been adequately analyzed in relation to soil-profile morphology. Fortunately, in 1955–1956, it was possible to conduct these studies in a small area about one mile south of the Arctic Research Laboratory, Point Barrow, Alaska, where the major regional genetic soils [*Tedrow* and others, 1958] are represented. Field measurements showed marked variations in temperatures and in the thickness of the active layer in these soils.

Arctic brown soil, which most commonly occurs on the higher topographic positions [*Drew* and *Tedrow*, 1957], is present on a well-drained, uplifted marine beach ridge. Because of its exposure to high winds, snow cover on this soil is limited throughout the winter and disappears earlier in the spring than from the nearby tundra and bog soils. Free internal drainage prevents arctic brown soil from accumulating very large quantities of ice. Its surface cover is favorable to absorption of radiant energy, and its low heat capacity permits thawing to begin much earlier and to progress much more rapidly than in adjacent poorly drained tundra and bog soils. Compared with soils on well-drained sites, their initial thaw is considerably delayed. When thawing begins in tundra and bog soils, it progresses at a comparatively slow rate because of their high specific heat resulting from high percentage of ice and lack of free internal drainage, and because of the insulating effect of their organic cover. Variations in plant communities correspond to these differences in soil conditions.

Methods—Observations were made on a sequence of soils located along a north-south transect (Fig. 1) from mid-June until the freeze-back. Depth of snow and of thaw were measured with a steel probe. Soil temperatures were determined in the three-inch depth with ordinary glass immersion thermometers left in place in the soil during the course of the investigation. Preliminary studies were made in 1955, but only the data collected during 1956 are here reported.

Vegetation was sampled by a line-plot-list technique using sample units two inches in diameter centered at four-inch intervals along the transect. Samples from such a small area permitted reasonable estimates of species importance from frequency of occurrence along a segment of the line.

The transect—Permafrost extends to a measured depth of 1030 ft near Point Barrow [*MacCarthy*, 1952]. Much of the land surface is underlain by a network of ground-ice wedges [*Black*, 1950]. High-center, non-sorted polygons [*Washburn*, 1956] containing large amounts of gravel appear along the old beach ridge (Fig. 1). The adjoining low areas of the transect consist primarily of silt and fine sand mantled with tundra and bog soils. Low-center, non-sorted polygons are associated with the tundra soil at the northern end of the transect. Since the polygonal pattern with its associated changes in micro-relief, vegetation, and soil moisture within short distances complicates the measurement of soil conditions, the transect was not extended into the polygonized area. Occasional measurements during the season indicated, however, that the average depth of thaw in the polygonized tundra soils corresponded to data obtained in the tundra soil portion of the transect. The bog soil south of the beach ridge shows little

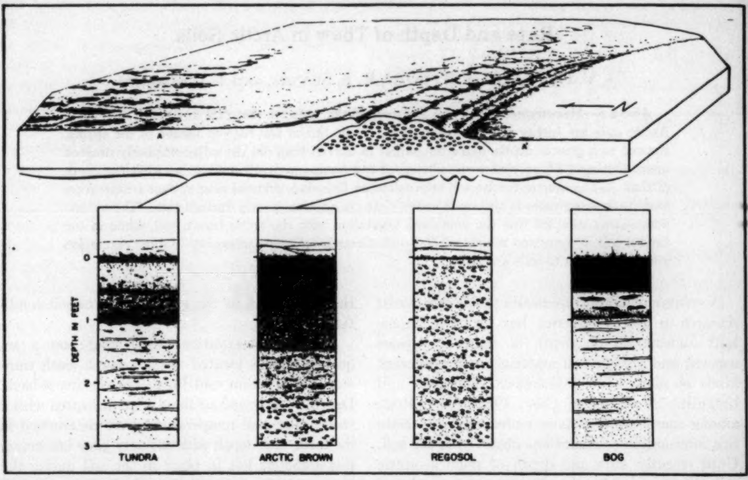

FIG. 1 – Diagram of soil conditions in an area one mile south of the Arctic Research Laboratory at Point Barrow Alaska; vertical scale in the diagram has been exaggerated; the transect shown in Figure 2 extends from A to A′

evidence of polygonization. A small, well-drained gravel terrace near the southern edge of the beach ridge lacks a well-developed profile and is classed as a regosol. The soil profiles (Fig. 1) occurring along the transect are in part idealized. The well-drained arctic brown soil occupies the elevated portion of the transect. The tundra soil is poorly drained, while the bog soil is associated with the poorest drainage in the area. The small terrace adjacent to the beach ridge, termed regosol, consists of well-drained gravel with no perceptible soil development.

The complexes of vegetation present along the transect are representative of the low-lying coastal portion of the Arctic Coastal Plain. Five major vegetation units are recognizable, each correlated with particular physiographic and edaphic factors recognized in the soil mapping units. The polygonized tundra soil north of the transect is characterized by a *Dupontia-Carex-Eriophorum scheuchzeri* complex. In the continuous ankle-deep sward, the arctic grass *Dupontia* characteristically occupies low-center polygon centers and troughs and the sedge *Carex aquatilis* the marginal ridges; the cotton-grass *Eriophorum scheuchzeri* is especially evident along their edges.

Tundra soil on the northern flank of the ridge supports a *Poa-Carex-Arctagrostis* complex which forms a more open sward of lower stature. The better-drained portion of this soil unit, while still grassy in aspect, is characterized by the dwarf round-leaved willow *Salix rotundifolia*, which becomes dominant in the next portion of the transect, and by the composite *Petasites*.

The crest of the ridge characterized by arctic brown soil, exposed and almost snow-free most of the winter, bears a low willow-lichen-moss complex which covers about 80 pct of the surface. At places, the vegetation mat is being removed by the wind, and raw humus and soil are exposed. A tight suppressed growth of lichens (*Cornicularia*, *Thamnolia*, *Sphaerophorus*, *Dactylina*), small clumps of *Luzula confusa*, and scattered plants of arctic bluegrass (*Poa arctica*) characterize this exposed area. On the sheltered south-facing portion of the ridge at the transect station 11 (Fig. 2), such showy-flowered species as *Papaver macounii*, *Pedicularis lanata*, and *Draba fladnizensis* occur, suggestive of the flower slopes elsewhere better expressed, but quite local in the region.

The regosol at the base of the ridge is characterized by discontinuous patches of mat-forming

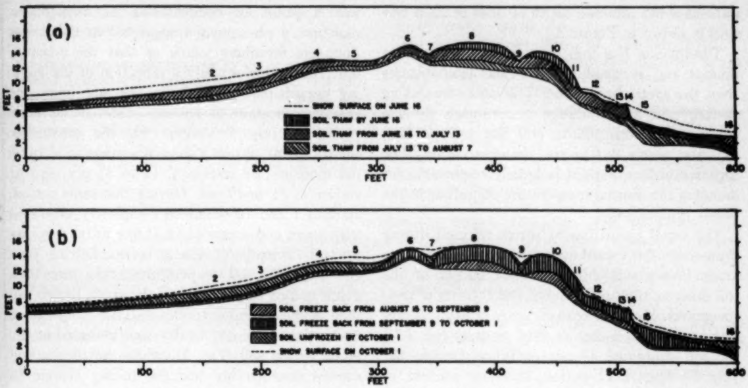

FIG. 2 – Frozen layer positions along the transect (a) shown at three time-intervals from the beginning soil thaw until the time of maximum thaw on August 7; most of the snow cover had disappeared by June 26; numbers along the surface of the profile indicate stations where readings were taken; (b) shown at three intervals from the beginning of freeze-back until October 1; snow began accumulating about September 23 and reached the level ndicated by October 1

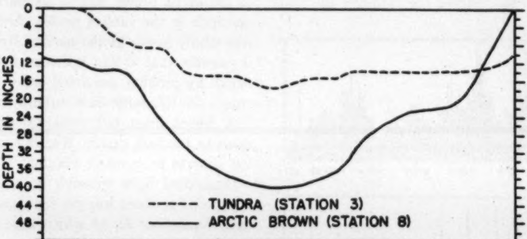

FIG. 3 – Comparison of rates and depths of thaw in arctic brown and tundra soils located on the transect shown in Figures 1 and 2

species, some of which tolerate salt and are found on present-day gravel beaches: *Cochlearia officinalis*, *Saxifraga nivalis*, *S. caespitosa sileneflora*, and *Cerastium beeringianum*.

The marsh vegetation developed on the bog soil at the south end of the transect is dominated by the marsh grasses *Dupontia* and *Arctophila* rooted in peat beneath a spongy carpet of moss. Large *Sphagnum* polsters and such herbs as *Saxifraga hieracifolia*, *S. cernua*, and *Cardamine* occur along the marsh edges.

Discussion—Arctic brown soil, the first to thaw, had thawed to a depth of 11 inches by June 16. The regosol on the small, well-drained gravel terrace (Fig. 2, station 14) was thawed to a depth of three inches by that date. Because of its slightly less effective drainage position and proximity to late-season snow cover, the regosol thaw lagged slightly behind that of the arctic brown. Tundra and bog soils along the transect remained covered with snow and did not begin to thaw until June 26, at which time most of the snow had disappeared. A maximum depth of thaw of 40 inches was found in the arctic brown soil on August 7 (Fig. 2, station 8), while in the tundra soil it was found to be 18 inches on August 11 (Fig. 2, station 3). A comparison of the rate and depth of thaw in these two soils is shown in Figure 3.

Tundra and bog soils pass through a narrower diurnal and seasonal range of soil temperatures than the arctic brown soil. The peaty insulating surface and the blockage of drainage by the frozen layer keep tundra and bog soils at high moisture levels during the thawing period. The higher moisture content is largely responsible for damping the diurnal temperature amplitude in the poorly drained soils.

The small quantities of water released during thaw move downward and escape downslope from arctic brown soil. Approximately 60 pct of the soil mass at the arctic brown site consists of pea-size gravel. Moisture release curves of the < 2 mm fraction indicated that at field capacity (pF 2.7), the soil contained 47 pct moisture. During the July 1 – August 12 period, moisture content in the arctic brown soil (< 2 mm) at station 8 (Fig. 2) varied between 3 and 26 pct. The moisture percentage did not always show a progressive decrease following rainfall; instead, it showed an erratic variation. It is possible that the moisture increase in the soil during the rain-free intervals was a result of condensation of atmospheric moisture, a phenomenon suggested in the Soviet literature for many years, or that the moisture differences were actually a reflection of the varying organic-matter levels in the soil from one sampling location to another. During the same period of July 1 – August 12, the gravel-free tundra soil at station 3 showed a range of 18 to 66 pct moisture; at station 4, 14 to 37 pct; and at station 6, 21 to 79 pct. During this same period, stations 1 and 16 remained completely saturated with water and commonly had free water covering the soil to depths of several inches. During June and early July, soil temperatures at the three-inch depth tended to be higher in the arctic brown soil than in the adjoining tundra soil. Air temperature fluctuations from day to day were reflected in the arctic brown soil (Fig. 4), while the tundra soil showed considerably less day-to-day change in temperature.

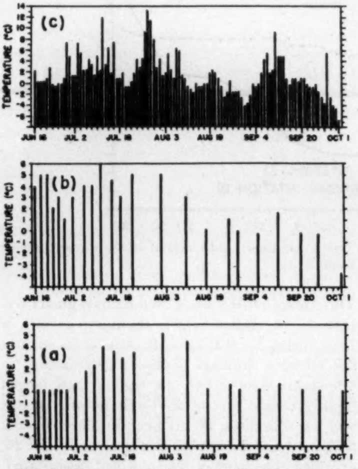

FIG. 4 – Temperature data (a) soil temperatures at the three-inch depth in tundra soil (station 3); (b) soil temperatures at the three-inch depth in arctic brown soil (station 8); (c) daily mean air temperatures from the U. S. Weather Bureau Station at Point Barrow, Alaska (1956)

The top of the frozen layer had begun to move up toward the surface by about August 23. On September 9, it was determined by probing with a steel rod that the frost table had risen 17 inches in the arctic brown soil in comparison with only one inch in the tundra profile. Arctic brown soil was solidly frozen to the surface by October 1 (it is possible that a thin unfrozen zone, difficult to detect by probing, persisted below a thick frozen crust). On this same date, tundra soil had a three-inch frozen crust but remained unfrozen at the three to ten inch depth. Weather conditions were too adverse to continue readings after October 1.

Occasional light snowfall occurred during the summer, but there was no significant snow cover until September 23, at which time it was limited to the tundra and bog soils. A saturated condition, combined with a surface accumulation of organic matter and snow, prevented the tundra soil from freezing as rapidly as did the arctic brown soil. Although the tundra soil thawed less than half as deep as the arctic brown soil, it lagged behind the latter in both thawing and freezing. The maximum depth of thaw in the bog soil was similar to that of the tundra soil. The greater total depth of thaw in the bog soil at the southern end of the transect (Fig. 2), in comparison with that of the wet soils of the northern end, is attributed to the action of light-tracked vehicles that operated daily within a few feet of the southern extremity of the transect.

Reconnaissance observations of the Alaskan Arctic Slope indicate that information on rate and depth of thaw associated with the major genetic soils near Point Barrow can be applied, with minor modifications, to other arctic areas where similar soils and vegetation occur.

Acknowledgments—Journal series paper of the New Jersey Agricultural Experiment Station, Rutgers University, the State University of New Jersey, Department of Soils, and contribution from the Botanical Laboratory, University of Tennessee, n. s. 183. These studies were aided by a contract between the ONR, Department of the Navy, and the Arctic Institute of North America.

On the Theoretical Derivation of Darcy and Forchheimer Formulas

S. IRMAY

Abstract—Darcy's law $\mathbf{q} = K\mathbf{J}$($\mathbf{q}$ = vector of specific discharge; $\mathbf{J} = -\text{grad}\, E$ = hydraulic gradient; E = energy of flow; K = hydraulic conductivity of porous medium) is historically reviewed as well as its numerous extensions. The author starts from the Navier-Stokes hydrodynamic equations of viscous flow, and using statistical methods (space averaging) shows that: The head (or energy) used in Darcy law is different from that used in viscous flow; which recommends large piezometric intakes. The formula $\mathbf{J} = a\mathbf{q} + bq\mathbf{q} + c\partial\mathbf{q}/\partial t$ is obtained (a, b, c = coefficients in isotropic media). Usually the third term may be neglected. At low values of Reynolds numbers, Darcy's law is obtained with $a = 1/K$ in the Kozeny-Carman form. It is found that a = the hydraulic resistivity is more important than K. At larger values of Reynolds number, the Forchheimer formula is obtained, with b depending on the soil texture (grain diameter d) and porosity, not on temperature nor viscosity. The Laplace equation is replaced by a non linear Poisson-type equation with $K = f(J)$. Darcy's law then becomes physically meaningless. A minimum principle is found: Darcy flow is such that the kinetic energy or the dissipation becomes minimum. The application of the Navier-Stokes equations to rocks with seams or cracks gives Darcy's law in its tensorial form.

Introduction—The steady flow of a viscous incompressible and chemically inactive fluid through a saturated homogeneous isotropic and geometrically stable porous medium in the absence of compressible free gases at low Reynolds numbers ($R = qd/\nu$) and at a constant temperature, obeys the Darcy law [*Darcy*, 1856; *Irmay*, 1946, 1947]

$$\mathbf{q} = -K\,\text{grad}\, h = K\mathbf{J} \tag{1}$$

$\mathbf{q}$ = specific discharge (that is, discharge per unit area, dimensions LT^{-1})
γ = unit weight of fluid
ν = kinematic viscosity
d = mean diameter of grains of porous medium
p = pressure
g = acceleration of gravity
Z = elevation above horizontal datum
K = hydraulic conductivity (dimensions LT^{-1}) [*Richards*, 1952] (measures the permeability of the porous medium to the fluid)
h = piezometric head (that is, combined gravity and pressure force potential)

$$h = Z + p/\gamma \tag{2}$$

$$\mathbf{J} = \text{hydraulic gradient} = -\text{grad}\, h \tag{3}$$

Darcy law was extended to non-homogeneous media [*Boussinesq*, 1904a; *Irmay*, 1953], to non-isotropic media [*Irmay*, 1951b; *Schneebeli*, 1953; *Ferrandon*, 1954], to geometrically unstable media [*Florin*, 1948; *Jacob*, 1950], to unsteady flow [*Boussinesq*, 1904b; *Irmay*, 1951a; *Polubarinova-Kochina*, 1952], to compressible fluids [*Muskat*, 1937], to unsaturated media [*Richards*, 1931; *Gardner*, 1946; *Irmay*, 1956a; *Budagovsky*, 1955], and to solutions and adsorptive media [*Edlefsen* and *Anderson*, 1942].

A detailed review of the various theories is given in some textbooks [*Muskat*, 1937, 1949; *Polubarinova-Kochina*, 1951, 1952; *Scheidegger*, 1957].

At larger Reynolds numbers *Forchheimer* [1901] suggested to replace (1) by the non-linear formula which bears his name

$$J = aq + bq^2 \tag{4}$$

See also *Lindquist* [1933]. At low $R(<1)$, the second term may be neglected, and the linear Darcy formula (1) is obtained. Here $a = 1/K$ = hydraulic resistivity of porous medium.

At medium $R(>1)$, the second term is of the same order as the first term. This is the case of a non-linear viscous flow. *Irmay* [1956b] has shown that there is no reason in general to expect a linear solution of the fundamentally non-linear Navier-Stokes equations. The linear Poiseuille solution in straight tubes is an exception caused by vanishing curvature. In flow through porous media the paths are strongly curved.

At larger R (>100) the flow becomes turbulent, as was experimentally shown by the injection of dyes [*Schneebeli*, 1955]. Eq. (4) remains valid, but with different values of a and b. At very large R, $a = 0$ (analogy with rough turbulent flow).

Smreker suggested a different relationship

$$J = Aq^n \; (1 < n < 2) \tag{4a}$$

and *Polubarinova-Kochina* [1952]

$$J = aq + bq^2 + cq^3 \tag{4b}$$

It will be shown later on that the Forchheimer formula is the only one that has a rational basis.

Applying the operation div to the vectorial equation (1)

$$\text{div } \mathbf{q} = -\text{div } (K \text{ grad } h) = 0 \tag{5}$$

In homogeneous media K is constant, and

$$\text{div grad } h = \nabla^2 h = h_{xx} + h_{yy} + h_{zz} = 0 \tag{6}$$

The terms $h_{xx} = \partial^2 h/\partial x^2$, etc. This is the well-known equation of the Laplace potential.

In media of non-uniform K variable in space (5) becomes [*Boussinesq*, 1904a]

$$\text{div } (K \text{ grad } h) = K\nabla^2 h + \text{grad } h \cdot \text{grad } K = 0$$

or

$$\nabla^2 h + \text{grad } h \cdot \text{grad } \ln K = 0 \tag{7}$$

h is a potential of the Poisson type [*Irmay*, 1953]. *Scheidegger* [1957] though, is not sure whether (1) should not be replaced by

$$\mathbf{q} = -\text{grad } (Kh) \tag{1'}$$

which instead of (7) gives

$$\nabla^2 (Kh) = K\nabla^2 h + 2 \text{ grad } h \cdot \text{grad } K + h\nabla^2 K = 0 \tag{7'}$$

Many authors tried to derive Darcy's law by means of various physical and ingenious models and analogies. An excellent review is given in *Scheidegger* [1957]. The models are the capillary-tube analogies [*Smith*, 1932; *Irmay*, 1951a]; the hydraulic-radius theories [*Terzaghi*, 1925; *Kozeny*, 1927; *Irmay*, 1951a]; the drag theories by Emersleben, 1924, 1925 [*Scheidegger*, 1957]; the statistical theories [*Hubbert*, 1940 (or Childs in 1950 and Taub in 1951); *Scheidegger*, 1957]; the thermodynamical theories [*Edlefsen* and *Anderson*, 1943]; the turbulent-flow analogy by Yuhara, 1954 [*Scheidegger*, 1957]; and by direct derivation from the Navier-Stokes equations [*Hall*, 1956; *Hubbert*, 1956].

The above theories have the weak point that they are mostly analogies, the applicability of which has not been proved, or they are based on the introduction of unspecified coefficients, which are somehow ignored in later developments. None of them lead towards Forchheimer's formula.

It will be shown that Darcy's law and even Forchheimer's law may easily be derived from the Navier-Stokes hydrodynamic equations, in the case of viscous flow through a homogeneous isotropic incompressible saturated medium.

Navier-Stokes equations of viscous flow—An incompressible viscous liquid in laminar flow obeys the equation of continuity

$$\text{div } \mathbf{V} = 0 \tag{8}$$

and the dynamic Navier-Stokes equations, summed up vectorially as

$$\mathbf{V}_t - \mathbf{V} \times \text{curl } \mathbf{V} + \text{grad } (V^2/2) = -\text{grad } (gh) - \nu \text{ curl curl } \mathbf{V} \tag{9}$$

where

$\mathbf{V}$ = velocity vector

$\mathbf{V}_t = \partial \mathbf{V}/\partial t$

t = time

$\mathbf{V} \times \text{curl } \mathbf{V}$ = vectorial product

Introducting the energy of flow per unit weight E (dimension L)

$$E = h + V^2/2g = Z + p/\gamma + V^2/2g \tag{10}$$

Eq. (9) becomes

$$\text{grad } (gE) = \mathbf{V} \times \text{curl } \mathbf{V} - \nu \text{ curl curl } \mathbf{V} - \mathbf{V}_t \tag{11}$$

The vectorial operation div gives

$$\text{div grad } (gE) = g\nabla^2 E = \text{div } [\mathbf{V} \times \text{curl } \mathbf{V}] = (\text{curl } \mathbf{V})^2 - \mathbf{V} \cdot \text{curl curl } \mathbf{V} \tag{12}$$

$\mathbf{V} \cdot \text{curl curl } \mathbf{V}$ is the scalar product. Because of (8)

$$\text{div } \mathbf{V}_t = (\text{div } \mathbf{V})_t = 0$$

$$\text{div curl curl } \mathbf{V} = 0$$

Re-written, (12) gives

$$g\nabla^2 E = g\nabla^2(h + V^2/2g) = (\text{curl } \mathbf{V})^2 - (\mathbf{V} \cdot \text{curl curl } \mathbf{V}) \tag{13}$$

At very low Reynolds numbers ($R = Vd/\nu$ with d = characteristic length), that is, when the velocity is very small, the inertia terms, which are of the second order in V, may usually be neglected, when compared to the gravity, pressure, and viscous forces. Approximately

$$\nabla^2 E = 0 \tag{14}$$

assuming $(\text{curl } \mathbf{V})^2$ and $\mathbf{V} \cdot \text{curl curl } \mathbf{V}$ negligible, as being of second order in $\mathbf{V}$. To the same degree of approximation, neglecting $V^2/2g$ we may write

$$\nabla^2 h = 0 \tag{15}$$

This formula holds for any slow viscous flow, it is therefore true for slow laminar flow through a porous medium, whether saturated or not, homogeneous, isotropic, or not.

Eq. (15) is identical with (6), yet the analogy is superficial. In (15), *h* represents the local head *h* at a single point of the viscous fluid flowing in the pores between grains. In (6), *h* represents the space-averaged head $\bar{h}$ in a volume containing a large number of grains and pores, yet small enough when compared with the size of the flow, so as to enable partial derivation. The true viscous and essentially rotational (that is, non-potential) inhomogeneous two-phase flow in the pores between the grains is replaced by a fictitious irrotational (that is, potential) flow through a homogeneous continuous porous medium. This medium is considered as if it consisted of a single phase. This is fiction but becomes true on the average in a sufficiently large volume. This explains why the intake heads of piezometric tubes in soils have to be as large as possible, if consistent data are required.

The discrepancy is even more striking between (15), which is valid also for the flow through the pores of an inhomogeneous medium, and the corresponding Boussinesq formula (7). It is apparent here that *h* has not the same meaning in both cases.

Derivation of the Darcy and Forchheimer formulas—Let us consider one-dimensional flow in the direction x through a homogeneous isotropic medium of average grain diameter *d* and porosity *n*, that is, ratio of voids to total volume of soil. It may easily be shown that this is also the average porosity in a cross section, or the porosity along any direction [*Rose*, 1943].

At any point of the pore space the flow obeys the Navier-Stokes equation (11). In spite of the hypothesis of overall one-dimensional flow throughout the porous medium, we have a three-dimensional viscous flow in the tortuous channels of the medium. In the direction x, (11) gives

$$\begin{aligned} gE_x = \tfrac{1}{2}(v^2 + w^2 - u^2)_x + (uv)_y + \\ (uw)_z - u_t + \nu(u_{xx} + u_{yy} + u_{zz}) \end{aligned} \qquad (16)$$

where x, y, z are the axes of a cartesian system of coordinates; u, v, w the corresponding components of the velocity vector **V**.

Let us now consider a volume, which is sufficiently large, so as to include a great number of grains, and that the conditions of overall homogeneity and isotropy are verified; yet, which is sufficiently small, so that its overall properties do not vary much within it. Let us compute the space average (represented in what follows by an overscore) of (16). The terms v, w are the transversal components. By reasons of homogeneity and isotropy they vanish on the average, as u is the main component. Hence

$$\left.\begin{aligned} &\bar{v} = 0; \quad \overline{w} = 0 \\ &\overline{uv} = 0; \quad \overline{uv_y} = 0; \quad \overline{uw} = 0; \quad \overline{uw_z} = 0 \end{aligned}\right\} \qquad (17)$$

Because of (8)

$$\left.\begin{aligned} u_x &= -v_y - w_z \\ u_{xx} &= -v_{xy} - w_{xz} \\ \overline{u_{xx}} &= -\overline{v_{xy}} - \overline{w_{xz}} = 0 - 0 = 0 \end{aligned}\right\} \qquad (18)$$

The specific discharge q in the direction x is (Fig. 1)

$$\left.\begin{aligned} q &= \bar{u}n \\ \bar{u} &= q/n \end{aligned}\right\} \qquad (19)$$

as n is also the average linear porosity in a direction normal to x.

If L is the average free distance between two grains

$$\left.\begin{aligned} &n = L/(L + d) \text{ or} \\ &L/d = n/(1 - n) \end{aligned}\right\} \qquad (20)$$

Because of the independence of time derivation and spatial integration

$$\bar{u}_t = q_t/n \qquad (21)$$

As the liquid adheres to the walls, there $u = 0$, and u passes through a maximum somewhere in between. Hence the surface $u\ (y, z)$ in a cross section of a pore channel between two grains turns its curvature towards negative x, hence, $u_{yy} < 0$; $u_{zz} < 0$. Averaging, and taking into account (19)

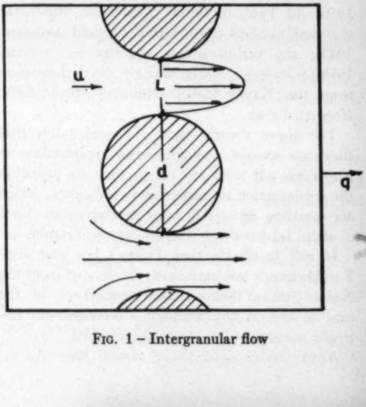

FIG. 1 – Intergranular flow

and (20), we can estimate

$$\bar{u}_{yy} = -\beta_1\bar{u}/L^2 = -\beta_1(1-n)^2/n^3\cdot q/d^2$$

$$\bar{u}_{zz} = -\beta_2\bar{u}/L^2 = -\beta_2(1-n)^2/n^3\cdot q/d^2$$

$$\bar{u}_{yy} + \bar{u}_{zz} = -\beta(1-n)^2/n^3\cdot q/d^2 \tag{22}$$

β_1, β_2, $\beta = \beta_1 + \beta_2$ are numerical shape factors which depend on the shape of the grains and their structure, but not on the porosity or diameter.

In view of (8)

$$\tfrac{1}{2}(u^2)_x = uu_x = -uv_y - uw_z\text{, or }\tfrac{1}{2}\overline{(u^2)}_x = 0 \tag{23}$$

The stream converges when it has to squeeze in between two neighboring grains (Fig. 1). As in the vena contracta $v = 0$, $w = 0$, in the converging zone

$$\overline{(v^2 + w^2)_x} < 0$$

At the large velocities which have to be considered when we study the quadratic terms, there is often separation of flow in the diverging zone, with a much milder degree of divergence than the former degree of convergence. Here $\overline{(v^2 + w^2)_x}$ is either 0 or mildly positive. Hence in both the converging and diverging zones on the average

$$\overline{(v^2 + w^2)_x} < 0$$

In view of (19) and (20) we can estimate

$$\overline{(v^2 + w^2)_x} = -\alpha\bar{u}^2/L = -\alpha(1-n)/n^3\cdot q^2/d \tag{24}$$

where α is a numerical shape factor.

The vector of hydraulic gradient is

$$\mathbf{J} = -\text{grad}\, E \tag{25}$$

and has the components J_1, J_2, J_3 along the axes x, y, z. Introducing (17) to (25) into (16)

$$\bar{J}_1 = -\bar{E}_x = aq + bq^2 + cq_t \tag{26}$$

Similarly

$$J_2 = -\bar{E}_y = 0;\ J_3 = -\bar{E}_z = 0 \tag{27}$$

$$\left.\begin{aligned} a &= \beta\cdot(1-n)^2/n^3\cdot\nu/gd^2 \\ b &= \alpha\cdot(1-n)/n^3\cdot 1/gd \\ c &= 1/ng \end{aligned}\right\} \tag{28}$$

We have thus proved several facts known from experience, and settled a number of controversial points:

(1) At low values of R and steady flow

$$\left.\begin{aligned} \bar{J}_1 &= aq;\ q = K\bar{J}_1 \\ K &= 1/a = gd^2/\beta\nu\cdot n^3/(1-n)^2 \end{aligned}\right\} \tag{29}$$

This is Darcy's empirical formula (1), with Kozeny's expression for K; a is the hydraulic resistivity introduced by the author [*Irmay*, 1953], who has shown its basic importance over the hydraulic conductivity K. Eq. (26) settles this problem.

The whole concept of hydraulic conductivity as defined by

$$K = q/J \tag{30}$$

(we write here J for $\bar{J}_1$ for simplicity's sake) becomes physically meaningless. It may be used only when defined as

$$K = 1/a \tag{31}$$

K as measured by (30) should be abolished from laboratory practice as a universal coefficient and replaced by a.

(2) At higher values of R and steady flow (26) gives

$$J = aq + bq^2 \tag{32}$$

This is Forchheimer's empirical formula (2). This settles the controversy concerning the correct relationship of J to q. The coefficient b depends on the porosity n as $(1-n)/n^3$, and on the average grain diameter d. Hence the effect of larger grains is here more pronounced than in the case of a, which depends on d^2 (larger effect of fines). Coefficient b does not depend on viscosity nor temperature effects, whereas a does so.

(3) The term cq_t caused by unsteady flow is unimportant [*Polubarinova-Kochina*, 1952]. This is independent of the diameter d or temperature. Its effects are felt only initially during a fraction of a second, and may be neglected.

(4) The general case of flow in space may be derived from (26), neglecting only the unimportant cq_t

$$\mathbf{J} = a\mathbf{q} + bq\mathbf{q} = (a + bq)\mathbf{q} \tag{33}$$

with the components

$$J_1 = (a + bq)q_1 \qquad \text{etc.} \tag{33a}$$

From (33)

$$\left.\begin{aligned} J &= (a+bq)q \\ q &= -a/2b + \sqrt{(a/2b)^2 + J/b} \\ \mathbf{q} &= \mathbf{J}/(a+bq) = \\ &\qquad \mathbf{J}/|(a/2) + (a^2/4) + J/b| = \mathbf{J}f(J) \end{aligned}\right\} \tag{34}$$

Applying the operation div to the last equation

$$\text{div}\,\mathbf{q} = \text{div}\,\mathbf{J}f(J) = f(J)\,\text{div}\,\mathbf{J} + \mathbf{J}\cdot\text{grad}\,f(J) = 0$$

$$\text{div}\,\mathbf{J} + \mathbf{J}\cdot\text{grad}\ln f(J) = 0 \tag{35}$$

Eq. (25) gives

$$\nabla^2 E + \text{grad } E \cdot \text{grad } \ln f(|\text{ grad } E\ |) = 0 \qquad (36)$$

This is equivalent formally to (7) when the head h is replaced by the energy E, and the hydraulic conductivity K by

$$F(J) = [a/2 + \sqrt{a^2/4 + J/b}]^{-1} \qquad (37)$$

Eq. (36) is an elliptic partial equation of the Poisson type. This may be solved by a method of *Khristianovich* [1940; *Polubarinova-Kochina*, 1951, 1952].

The principle of minimum—Mathematically (6) is equvalent to the minimum of the integral throughout the volume T of flow [*Courant* and *Hilbert*, 1931]:

$$\int_{(T)} (\text{grad } h)^2 dT = \text{minimum} \qquad (38)$$

or, because of (1)

$$\int_{(T)} q^2 dT = \min \qquad (38a)$$

Darcy flow through a porous medium is such, that the total kinetic energy of flow is minimum; or such, that the dissipation of energy is minimum; as it is proportional to q^2.

This 'minimum principle' seems paradoxical: did not we neglect all second order terms in order to obtain it? And here the flow is conditioned by q^2. The answer is quite simple: second order terms may be neglected, when there are other terms much larger; but one must not neglect such a term, when there is no other. This principle is valid also in Darcy flow in inhomogeneous and non-isotropic media, yet it is not valid, for example, in Forchheimer flow.

Derivation of Darcy's law for media with seams or cracks—The author has applied the Poiseuille solution to the flow in the seams and cracks of cracked rocks, the seams assumed to be straight [*Irmay*, 1955]. In the case of three orthogonal systems of identical and equidistant parallel seams or cracks, Darcy's law is obtained, with the hydraulic conductivity in the Kozeny-Carman form. When the three systems of seams or fractures are geometrically different or inclined, K becomes a symmetrical tensor of rank two, the elements of which are determined by the geometry of the seams. Such a fissured medium is a fair approximation to a non-isotropic porous medium.

Acknowledgment—Thanks are given to M. Schiffer of Stanford University and F. Ollendorff of the Technion in Haifa, for constructive suggestions.

The Measurement of Thermal Conductivity and Diffusivity with Cylindrical Probes

J. C. JAEGER

Abstract—The way in which the temperature of a thermal-conductivity probe (a heated cylinder in an infinite medium) approaches its logarithmic asymptote is discussed. Previous results of Buettner are criticized, in particular his conclusion that it is impossible to measure diffusivity by the use of cylindrical probes. An improved method of determining linear asymptotes for this purpose is described.

Introduction—A recent paper by *Buettner* [1955] discusses the possibility of measuring thermal conductivity and diffusivity by the use of a cylindrical test body or probe. Such methods, which are now assuming considerable importance, are based essentially on the result that if heat is supplied continuously at the rate Q per unit length per unit time for times $t > 0$ along an infinite straight line in an infinite medium initially at zero temperature, the temperature v at time t at distance r from the line is given by

$$\frac{Kv}{Q} = -\frac{1}{4\pi}\,\mathrm{Ei}\left(-\frac{r^2}{4\mathrm{K}t}\right) \tag{1}$$

where K and K are, respectively, the thermal conductivity and diffusivity of the medium, and $-\mathrm{Ei}(-x)$ is the tabulated exponential integral.

For large values of $\mathrm{K}t/r^2$, (1) becomes

$$\frac{Kv}{Q} = \frac{1}{4\pi}\ln\frac{4\mathrm{K}t}{Cr^2} + \frac{r^2}{16\pi\mathrm{K}t}\cdots \tag{2}$$

where $C = 1.7811\ldots$, that is, for large values of $\mathrm{K}t/r^2$, the curve of v against $\ln t$ becomes asymptotically a straight line of slope $Q/4\pi K$ and intercept $\ln(Cr^2/4\mathrm{K})$ on the $\ln t$ axis. Thus any measurement of temperature in a system of this type leads immediately to a determination of K, and, in principle, also of K. Essentially similar results hold for a distribution of parallel line sources as well as for more complicated systems involving composite media and contact resistances.

For measurements in soils, needle probes of small diameter are used. In such cases the linear asymptote is approached in intervals of the order of minutes, and the additional advantage is claimed that in such intervals heat penetrates only into a small portion of the medium so that the conductivity of the material in the immediate neighborhood of the probe is measured. In these cases the quantity r in (2) is a very indefinite one so that there is no possibility of measuring K accurately with a single probe of small diameter.

Blackwell [1954] has studied the problem of making measurements in rock by means of a larger probe inserted into drill holes. In this case the diameter of the probe is several centimeters, and the time taken to reach the logarithmic portion of the curve is a matter of hours. The penetration of heat into the rock is considerable, so that in this case an average conductivity over a region is measured; this is the most useful result for geophysical applications. In this case, the physical system is very nearly the ideal one of a circular cylinder of radius a of perfect conductor of thermal capacity S per unit length to which heat is supplied at the rate Q per unit time per unit length and which is in perfect thermal contact at its surface with an infinite medium of thermal constants K and K. This is the simplest idealization of the probe and has been considered by *Carslaw* and *Jaeger* [1947, p. 284], *Van der Held* and others [1953], *Buettner* [1955], and *Jaeger* [1956]. It is easy to extend it to allow for contact resistance at the surface of the cylinder [*Blackwell*, 1954; *Jaeger*, 1956] or to the case of finite conductivity of the probe [Blackwell, 1954] but at the expense of introducing additional parameters. These more complicated cases will not be discussed below, but they may be treated along the same lines.

Numerical results for a perfectly conducting probe with perfect thermal contact at its surface—For the system described above, the temperature v of the perfect conductor for large values of the parameter $\mathrm{K}t/a^2$ is given by

$$\frac{Kv}{Q} = \frac{1}{4\pi}\left\{\ln\frac{4\mathrm{K}t}{Ca^2} + \frac{a^2}{2\mathrm{K}t} + \frac{(\alpha-2)a^2}{2\alpha\mathrm{K}t}\ln\frac{4\mathrm{K}t}{Ca^2} + \cdots\right\} \tag{3}$$

where $\alpha = 2\pi a^2 K/S\mathrm{K}$.

Thus the slope of the asymptote of the curve of v against $\ln t$ gives K and its intercept gives K/a^2. Provided a is not too small, the only difficulty in

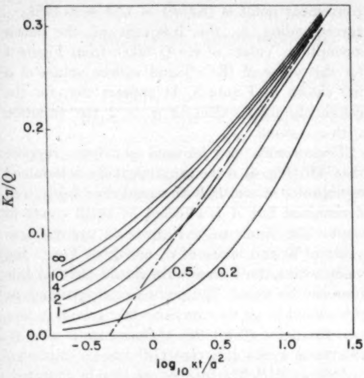

FIG. 1 – The variation of temperature with time for a heated cylinder surrounded by an infinite medium; numbers on the curves are the values of α; all curves have the same asymptote (shown dotted)

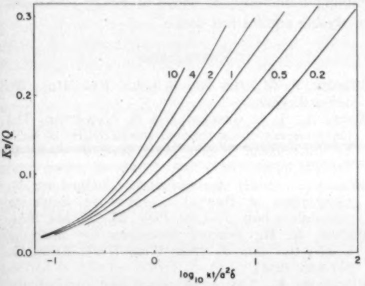

FIG. 2 – The results of Fig. 1 plotted in the manner of *Buettner* [1955]; numbers on the curves are values of $\delta = 2/\alpha$

determining K by this method is that the asymptote is determined at the larger values of $\ln t$ and small errors in its slope may affect the intercept seriously. This point will be discussed later.

Formulas for the temperature at smaller values of the time have been given by the authors referred to above. *Jaeger* [1956] has given some numerical values for such times, but it appears that there are considerable discrepancies between these and Figure 3 of *Buettner* [1955] and the object of the present note is to point out these and their effects on Buettner's conclusions.

Figure 1 shows values of (Kv/Q) plotted against $\log_{10}(\mathrm{K}t/a^2)$ for various values of α. These are mostly taken from *Jaeger* [1956]. The way in which the curves approach the asymptote is seen to be rather complicated, particularly for small values of α, say $\alpha < 1$, when the curves show an inflexion which might easily be mistaken for an asymptote in a short experiment.

In Figure 2 the same quantity Kv/Q is shown plotted against $\log_{10}(\mathrm{K}t/a^2\delta) = \log_{10}(\pi Kt/S)$ for various values of $\delta = 2/\alpha$. This is the plot used by *Buettner* [1955] and this figure is directly com-

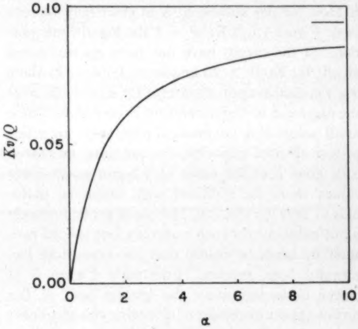

FIG. 3 – Values of Kv/Q as a function of α for $(\mathrm{K}t/a^2) = C/4 = 0.4453$

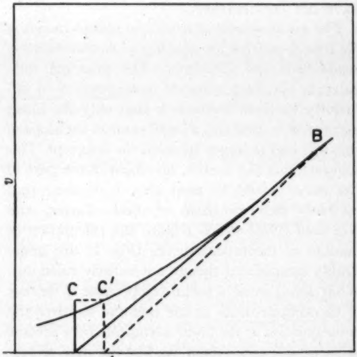

FIG. 4 – Method of using the results of Fig. 3 to improve the determination of an asymptote

parable with his Figure 3. There are very important discrepancies between the two figures, in particular, Buettner's curves for the range $1 < \delta < 10$ lie close together, and from this he concludes that in this range (which includes most practical cases) the rise in temperature of the cylinder depends only on K and very little on δ or the thermal capacity of the soil, so that the thermal capacity of the soil cannot be measured in this way. It appears from Figure 2 that this region is in no way peculiar and these conclusions do not hold.

Buettner further states that in the range $1 < \delta < 10$ the curves are logarithmic for $\mathrm{K}t/a^2 > \delta$. How far this statement is in error may be seen from Figure 1; for $\mathrm{K}t/a^2 = 1$ the logarithmic portions of the curves have not been approximated at all; for $\mathrm{K}t/a^2 > 20$ and $\alpha > 1$, ($\delta < 2$) there is a reasonable approximation; for $\alpha < 1$, ($\delta > 2$) the approach to the asymptote is very slow. These small values of α can occur in practice in materials of low thermal capacity, for example, powdered cork gives α of the order of 0.2 and much lower values would be obtained with expanded materials of very low density. The use of probe methods is not ruled out for such materials, but special care must be taken to ensure that the asymptote has actually been reached. Buettner's Figure 3 is rather misleading since the greater part of the curves appear to consist of diverging straight lines; in fact they all tend to parallel linear asymptotes and most of the field of his Figure 3 corresponds to values of the time in which these asymptotes have not been reached.

The use of theoretical results for smaller values of the time to improve the accuracy of measurements of conductivity and diffusivity—The principal difficulty in obtaining accurate measurements of diffusivity by these methods is that only the linear asymptote is used and a small error in the slope of this will lead to larger errors in the intercept. This suggests that the earlier, non-logarithmic part of the curve should be used also. It is clear that methods such as those of *Beck, Jaeger,* and *Newstead* [1956] which require the calculation of families of theoretical curves (Fig. 1) are undesirably complicated though not entirely ruled out. What seems to be a useful compromise is the use of theoretical values at one point to improve the determination of the linear asymptote by a process of successive approximation. For the case of perfect thermal contact discussed above, the most convenient point is $(\mathrm{K}t/a^2) = C/4 = 0.4453\ldots$ corresponding to the intercept of the linear asymptote. Values of Kv/Q taken from Figure 1 for this value of $(\mathrm{K}t/a^2)$ and various values of α are shown in Figure 3. It appears that for the commonly used values of $\alpha > 2$ the variation with α is small.

These results may be used as follows: suppose that AB (Fig. 4) is the experimentally determined asymptote, of which B is regarded as fairly well determined but A is affected by small errors in slope. The intercept OA gives an approximate value of K and hence of α, and from Fig. 3 the value which the temperature should have at this time can be found. The point C corresponding to this should lie on the experimental curve; if it does not, the point C' for this temperature is used to determine a new intercept OA' and an improved asymptote $A'B$. The process can then be repeated. Clearly, this simple process may be applied to any case in which an accurate determination of the intercept of a linear asymptote is required as in the time-lag methods of *Barrer* [1939] for determining diffusivity, or those of *Brown* [1953] for analysing aquifer test data.

Velocity of Compressional Waves in Some Indian Rocks*

S. BALAKRISHNA

Abstract—Velocities of compressional waves have been measured for samples of Indian rocks by direct measurement of times of pulse transmission. These are compared in a number of cases with measurements for the same rocks by the 'wedge' method and by the method of 'critical transmission.' It is concluded that the two latter methods are unsuitable for coarse-grained rocks composed of highly anistropic crystals.

Several studies of wave velocities in Indian rocks have been published [*Prasadarao*, 1947; *Balakrishna*, 1952, 1953; *Krishnamurthi* and *Balakrishna*, 1953; see also *Balakrishna*, 1955]. These have made use either of the 'wedge' method, in which a piezoelectric quartz wedge is used to excite thickness vibrations in a thin plate of sample, [*Bhagavantam* and *Bhimasenachar*, 1944], or the method of 'critical transmission', originated by *Bez-Bardili* [1935] as adapted by Krishnamurthi and Balakrishna. Both of these methods have given reliable results for homogeneous samples (single crystals, glasses) or fine-grained, quasi-isotropic metals; when, as for coarse-grained rocks, the crystal dimensions approach or exceed the sample thickness, the validity of these methods becomes doubtful, and indeed large discrepancies appeared in some cases between measurements for the same rocks by these two methods. It thus seemed desirable to obtain the velocity for some of these rocks by direct measurements of time of transmission of microsecond pulses through samples of a size large enough to afford reasonable average values.

The experimental arrangement has been described by *Tocher* [1957]. A rectangular electrical pulse of duration of about one microsecond, applied across a barium titanate transducer, imparts a compressional pulse to one face of the sample, a prism of rock with ground flat faces. An identical transducer on the opposite face receives the mechanical pulse and supplies an electrical signal to an amplifier and oscilloscope. The trigger pulse is also fed to a Type 326 DuMont time-delay generator; this is used to measure directly the time interval between the start of the electrical pulse and the start of the transmitted pulse. The times are exact to about 0.1 microsecond, of a total travel time of the order of ten microseconds.

TABLE 1.–*Velocities of compressional pulse by time-distance measurement*

and a sampling error, increasing as the size of sample is reduced, is to be expected. The samples studied by the wedge method and by critical transmission are only a few millimeters thick, to be compared with path-lengths of the order of 50 mm for the transmission-time measurements. In addition, the simple theory becomes seriously inadequate for the wedge and critical transmission methods when the sample consists of a small number of large crystals, having different orientations or different properties.

The comparative values of Table 2 are in general accord with these expectations. Fair agreement by all methods is shown for several of the rocks of finest grain: the sandstone, limestone, and trap. The wedge method on the whole shows better agreement with the direct time measurements than does the critical transmission method, which furnishes widely aberrant values for the coarse-grained granites, charnokite, and marble. These methods, wedge and critical transmission, are especially valuable for small samples of homogeneous material; they are evidently unsuitable for coarse-grained rocks.

The author desires to express his grateful thanks to Francis Birch for his helpful suggestions and guidance, and for the use of the equipment for the measurement of transmission times.

K-A and Rb-Sr Methods and Age of Precambrian of USSR

A. A. POLKANOV AND E. K. Gerling

Abstract—The procedure of mica age determination by the K-A method is described. The age data obtained by the K-A and Rb-Sr methods for Precambrian of the USSR together with their estimation are given. The data obtained are compared with the stratigraphy.

Our work was carried out by the K-A method since 1951 and by the Rb-Sr method since 1956. It is found that micas give the most reliable results. The evolution of argon from micas is connected with the great value of the activation energy, which may be compared with the energy of the bonds of the most stable chemical compounds. The activation energy found for the evolution of argon from muscovite, biotite and phlogopite is [illegible]5,000, 57,000, and 65,000 cal per gram atom argon respectively [*Gerling* and *Morosova*, 1957].

The evolution of argon is accomplished by the heating of micas for five hours at the temperature of 1200°C. The argon evolved is measured on a MacLeod manometer after the absorption of the chemically active gases and the separation from helium. The content of the air argon in samples is measured on the mass spectrometer with the aid of the isotope A^{36}. It was found that together with the evolution of argon from fluorine containing micas the formation of a molecular compound of argon takes place and the part of argon or even its whole amount is absorbed in the trap with liquid air. It was set so that by the heating of fluorine containing micas the mixture of silanes with the predominance of light SiH_4 evolved from these micas. The absorption of argon by liquid air takes place only in the presence of water vapor and silanes. Silane with water forms a molecular compound of the type SiH_46H_2O with which $A6H_2O$ crystallizes isomorphically. If the gases from micas are passed over the copper oxide at 600°C the silanes will oxidize and the formation of this compound in the trap with liquid air will not occur [*Koltzova*, in press].

The determination of K is made by the chloroplatinate and perchlorate methods. Rb is determined by application of radioactive tracers [*Jaschenko* and others, in press] or by the method of isotopic dilution. When calculating the age, the value of the electron capture disintegration constant of 6.02×10^{-11} year $^{-1}$ is used. This constant was calculated by us by means of the argon determination in micas the ages of which were obtained by the Pb method. For the beta emission disintegration constant of K^{40} the value of 4.9×10^{-10} is used.

Since 1951 more than 300 determinations of age of micas from different regions of the Precambrian of the USSR were made (M. L. Jashchenko, G. M. Ermolin, L. K. Levsky, L. I. Afanasieva, G. V. Ovchinnikova, T. V. Koltsova, I. M. Morozova, I. I. Matveeva, and V. D. Bugrova). Some of the data obtained were published by *Gerling* [1956] and *Gerling* and other [1955, 1957].

Some age determinations of rocks obtained by the K-A method on micas collected by geologists D. A. Velikoslavinskii, K. O. Kratz, V. A. Maslenikov, S. V. Obrutchev, N. G. Sudovikov, K. A. Shurkin, and others are shown in Table 1.

The age of the Precambrian of different districts of the USSR ranges from 2880×10^6 to 500×10^6 years. The oldest rocks are found on the Kola Peninsula. For some gneisses and granites age values of 2600×10^6 years were obtained. One of the age values is even 2880×10^6 years. It should be noted that for the Mesozoic and Paleozoic rocks there was no great divergence between the K-A method and stratigraphy in any case. Usually a good agreement in the data of both methods was obtained, the divergence with the geological data being insignificant.

However, the figures for the Precambrian given in Table 1 show the great difference between the age of some rocks by the K-A method and the geological data. Sometimes this difference reaches 10^9 years. We believe that this disagreement in the age of Precambrian is not connected with the incorrectness of the K-A method as is shown by the numerous age determinations of rocks from the Paleozoic era, and younger, and also by some comparative data between the K-A, Rb and Rb-Sr methods for the Precambrian of Ukraine and Siberia.

The samples in which the difference with the geological data was very great were examined. The age of the upper Proterozoic rapakivi granites of the

TABLE 1 – *Data on age determinations*

No.	Mineral	Locality	Geological age	Age in 10^6 years
1	Biotite from granite	Kola Peninsula, region of the m. Shulwave	Lower Archean	2880
2	Biotite from gneiss	Kola Peninsula, River Voronya	Lower Archean	2650
3	Biotite from granite with microcline	Kola Peninsula, River Voronya, Rapids Dyavolov	Lower Archean	2600
4	Biotite from gneiss of Polmas suite	Kola Peninsula, region of m. Shulwave	Lower Archean	2170
5	Biotite from gneiss of Polmas suite	Kola Peninsula, Kontozero	Lower Archean	2300
6	Biotite from plagioclase-microcline granite	Kola Peninsula, region of Porkozero	Lower Archean	2230
7	Mica from pegmatite	Kola Peninsula, m. Okhmilk, vein N 3	Lower Archean	2250
8	Mica from plagiogranite	Ukraine, Krevoy Rog	Lower Archean	1990
9	Mica from pegmatite of plagioclase granites	Ukraine, region of the village of Petrovo	Lower Archean	1980
10	Mica from gneisses	Ukraine, region of the village of Petrovo	Lower Archean	1980
11	Muscovite from pegmatite	Ukraine, Gitomir District, village Glubotchek	Upper Archean	1840
12	Muscovite from pegmatite	Ukraine, town of Korostichev	Upper Archean	1810
13	Mica from schists	Ukraine, village Appovka, Krivorogye	Lower Proterozoic	1820
14	Mica from the red granite intersecting the schists of the Krivorogye formation	Krivorogye, Balka Gladovoy, Ukraine	Lower Proterozoic	1860
15	Mica from gneiss	Karelia, Mine Karelsky, Kopatvaraka	Upper Archean	1850
16	Muscovite from pegmatite	Karelia, Tchkalov mine, vein of the 8th of March	Upper Archean	1740
17	Mica from the fine grained granite	Karelia, Archipelago Kandalakshsky Island Demenikha	Upper Archean	1890
18	Biotite from the gneiss of Anabarsky shield	Siberia, upper part of River Kenady	Archean	1900
19	Phlogopite	Siberia, Aldansky Shield, mine Taegenoy	Archean	1790
20	Phlogopite from metasomatic vein	Siberia, Aldansky Shield, Kurum-Khanku	Archean	1840
21	Biotite from gneiss intersected by metasomatic vein	Siberia, Aldansky Shield, River Tchuga	Archean	1870
22	Muscovite from pegmatite	Siberia, Cape Tiganoss	Archean	1700
23	Biotite from the schist of the Ladoga formation	Karelia, North Preladogye, western beach of the Cape Iminiemy	Lower Proterozoic	1640
24	Muscovite from the granite injected in the schists of Ladoga	Karelia, North Ladoga	Lower Proterozoic	1620
25	Muscovite from the schist	Karelia Lake Pukhya-Jarvy	Lower Proterozoic	1660
26	Biotite from quartz-biotite-amphibolic schist	Karelia, Parandovo	Lower Proterozoic	1650
27	Biotite from the schist	Karelia, village Guimaly	Lower Proterozoic	1740
28	Mica from the Korostene massive rapakivi granite	Ukraine, Korostensky massive	Upper Proterozoic	1660
29	Micas from the Viborg massive rapakivi	Baltic Shield, Viborg	Upper Proterozoic	1520
30	Mica from syenite of the Mariupole Complex	Ukraine, village Oktyabrskoe	Upper Proterozoic	1470
31	Biotite from granite	Kola Peninsula, Region Kontozero	Lower Proterozoic	1110
32	Glauconite	China, Sinian formation	Upper Proterozoic	650
33	Muscovite from pegmatite	Siberia, Region Birussinsky, mine Neroy II	Upper Proterozoic	492
34	Phlogopite from vein	Siberia, Sludyanka	Archean	462
35	Muscovite from pegmatite	Siberia, Mamsky region, mine Severny	Lower Proterozoic	337

Korosten Complex of the Ukraine, was equal by the lead method on the zircons to 1700 × 10^6–1750 × 10^6 years and by the K-A method to 1660 × 10^6 years (No. 28 in Table 1). These values agree between themselves quite well.

The K-A age of the Archean phlogopite from Sludyanka, Siberia, (No. 34) of 462 × 10^6 years is quite near to the Pb^{207}/Pb^{206} age of the zircon (450 × 10^6 yr) and to the Pb^{208}/Th^{232} age of the monazite (500 × 10^6 yr). (The Pb ages were determined in the V. I. Vernadsky Institute of the Analytical Chemistry and Geochemistry of the Academy of Sciences of the USSR [*Vinogradov* and others, 1957; *Girova* and others, 1957].

Micas of the Lower Proterozoic age of the Mamsky region of Siberia are dated according to the K-A method as 337 ×10^6 years and according to the Rb-Sr method as 420 × 10^6 years.

Mica from the Kola Peninsula, from the formation related to the Lower Proterozoic is dated according to the K-A method as 2200 × 10^6 years and according to the Rb-Sr method its age ranges from 2200 × 10^6 to 2600 × 10^6 years [*Jashchenko* and others, in preparation].

The above-mentioned examples show that the age data of mica from the rapakivi granite and of the micas from the pegmatite Mama and Birussa region in Siberia are not connected with the excess of argon or with its loss. The other problems of the K-A method, in the case where the age of the pegmatite mica proved to be 1000 million years older than the age of the mica from the gneiss intersected by the pegmatite, are now being examined. Polkanov believes that further research by the K-A method may put forward the question of the Precambrian of the Baltic and Ukrainian shields belonging to different periods of the Archean, with an age of over 1500 million years, and of the 'archeische Scheitel der Asia' (E. Suess), Siberia, to the Proterozoic-Paleozoic era, with the age of under 500 million years respectively.

An Optical Method for the Measurement of Surface Waves in the Laboratory*

ALAN J. FALLER

Abstract—The heights of surface waves in a laboratory experiment may be observed by variations in the absorption of light as it passes vertically through the fluid. With uniform illumination through the glass bottom of a tank the optical path length through a black dye solution may be recorded photographically from above the tank and the heights of surface waves may be measured from the film density. A linear relation between film density and wave height is possible if the 'straight-line' region of a film blackening curve is used and if the dye has a sufficiently constant absorption coefficient in the band of significant wave lengths. Optimum results are obtained by using as strong a concentration of dye as the intensity of illumination permits and by selecting a film with maximum contrast. In a simple experiment it was found possible to measure variations of the height of the free surface of the fluid to an accuracy approaching one per cent of the total depth, but significantly greater precision may be possible by using more elaborate apparatus.

Introduction—In a large variety of laboratory experiments involving gravity waves both at the free surface of a fluid and at the interface between two fluids it is desirable to have precise measurements of the wave structure; for example the waves produced by or which interact with towed ship models, waves created by the action of wind stress, or internal gravity waves which may exist in stratified models of oceans, rivers, or lakes.

This particular study was motivated by a desire to measure the height of the interface of two fluids in a two-layer atmospheric model developed by *Fultz* [1952] at the University of Chicago. In this model it is possible to represent the polar dome of cold air and the wave cyclones that occur along frontal surfaces in the atmosphere. The precise details of the generation of these waves at the interface of the two fluids are adequately described in the above reference and are not significant to the particular technique developed here.

The essence of the optical method by which these waves were to be measured was to provide a glass bottom in the circular tank, and to illuminate the fluids uniformly from below, so as to photograph the variations of optical density from above. In this technique the resultant film density could be calibrated as a function of the vertical thickness of the dyed fluid (either the lower or upper fluid), and the detailed shape of the interface of the two fluids could be determined from analysis of the film density pattern with a microdensitometer.

In an attempt to reproduce this model and to measure the depth of the interface, optical difficulties were encountered which rendered the method impractical for this particular experiment. Because of the necessarily small difference in the specific gravities of the two fluids (adjusted to a difference of 0.005), a colloidal suspension of water droplets was produced in the mixture of chlorobenzene and toluene (water being the less dense fluid and the mixture the more dense). In addition a detergent was required to reduce the interfacial tension between the two fluids and the problem was complicated by a precipitate from the detergent. The optical technique seemed to have more general applicability, however, and was developed further for the measurement of surface waves on water.

THEORY

The relation of film density to depth of liquid—In the following discussion it will be assumed that there is sufficient illumination to work in the 'straight-line' portion of a film response curve, that is, where the film density D is linearly related to the logarithm of exposure [see for example *Neblette*, 1938, or other texts on photographic theory]

$$D = C_0 \log (\text{exposure}) + C_1$$

In terms of film and illumination characteristics this statement becomes

$$D = \gamma \log \int C_2 P_{0\lambda} S_\lambda e^{-k_\lambda^{\,s}} t \, d\lambda + C_1 \tag{1}$$

where γ is the slope of the film response curve; C_1 includes the base density of the film and the inertia of the emulsion; S_λ is the sensitivity of the film to radiation of wave length λ; $P_{0\lambda}$ is the relative illuminating power per unit wave length incident on the bottom of the wave tank; C_2 accounts for losses by reflection at the interfaces of air, glass, and water; k_λ is the absorption coefficient per unit wave length; t is the duration of the exposure; and z is the geometric path length in the dyed fluid. If k_λ equals a constant $\bar{k}$, (1) may be written in the form

---

* Contribution No. 945 from the Woods Hole Oceanographic Institution.

$$D = -\gamma \bar{k} z \log e + \gamma \log t + \gamma \log \cdot \int C_2 P_{0\lambda} S_\lambda \, d\lambda + C_1 \quad (2)$$

For constant values of $P_{0\lambda}$, S_λ, C_2, t, and C_1 (that is, constant experimental conditions) we deduce the following linear relation between D and z

$$D = -(\gamma \log e) \bar{k} z + C \quad (3)$$

which may be differentiated to obtain

$$\frac{\partial D}{\partial z} = -\gamma (\log e) \, \bar{k} \quad (4)$$

From the above it is clear that the maximum sensitivity of density change to depth change exists for maximum values of γ and $\bar{k}$ and that it is desirable to use as high a concentration of dye as possible and a film which may be developed to high contrast.

It is important to note that appreciable changes in the value of $\bar{k}$ may require unreasonably large changes in the intensity of illumination required to produce the same film illumination P. Suppose the dye concentration is doubled and x is the factor by which P_0 must be increased to produce the same value of P. Then

$$P = P_0 e^{-\bar{k}z} = (xP_0) e^{-2\bar{k}z}$$

$$x = e^{+\bar{k}z} = P_0/P$$

In a particular example described below P_0/P = 48; therefore the illumination would have to be increased by this factor to double the sensitivity by increasing the dye concentration. Greater variations may be had through variation of the film contrast.

Errors caused by refraction and internal reflection—Because a ray path through the dye solution passes obliquely and with varying angles through the air-fluid interface there are inherent errors due to refraction and internal reflection. To simplify the discussion it will be assumed that the camera is sufficiently far from the water surface that the effect of the viewing angle of the camera may be neglected.

A simple consideration of the refraction due to the slope of waves using Snell's Law shows that for a wave slope of angle i the percentage error in the total depth of the fluid is as given in Table 1.

TABLE 1 – *Refraction errors at an air-water interface*

i	error
°	pct
10	0.1
20	0.3
30	1.0
40	1.9
50	3.4

The significance of these errors depends upon the accuracy required and the amplitude of the waves with respect to the total depth of fluid, but it is apparent that for many problems this error may be small enough to be neglected. If it should be necessary to apply a correction for refraction, the approximate wave slopes could first be determined and the correction applied as a second order effect. However it would also be necessary to consider the viewing angle of the camera if this angle deviated appreciably from the normal.

A computation of the reduction in light intensity caused by the variation of internal reflection with angle of incidence from Fresnel's formulas showed that this effect is generally small compared to the refraction effect and may be neglected in all cases except for extremely steep waves. In a two-layer model, errors caused by refraction and internal reflection would be negligible because large incident angles would occur only at the interface of the two fluids where the difference between indices of refraction would be much smaller than at an air-water boundary.

An alternate method of conducting experiments would be to illuminate from above and to photograph from below so that the path length through the fluid would not depend upon refraction at the disturbed air-fluid interface. Most experimental arrangements, however, would not permit the use of a camera at a sufficient distance beneath the apparatus.

Errors caused by inaccurate exposure time and uneven illumination—From (2) it is apparent that a change in the duration of exposure t would not affect $\partial D/\partial z$ and would only add a constant density correction to the entire film. Such an error would be easily recognized in the average density, and the correction could be determined by assuming that the average depth of water was the same over the observed area with and without waves. Of course it is necessary to use a sufficiently rapid exposure that the waves to be observed do not move a significant fraction of their wave length in the exposure interval. For the example discussed below the speed of gravity waves would have been approximately 50 cm/sec and in the exposure interval of 1/200 sec the waves would have moved only 0.25 cm compared to an observed wave length of 13 cm.

Errors produced by uneven illumination from below may be determined by a 'null' experiment, that is, no waves. It is again evident from (2) that $\partial D/\partial z$ is independent of $P_{0\lambda}$ and the additive correction to D is a function of position alone. In the experimental example below this correction was applied by graphical subtraction of the 'null' contours from the wave contours.

Note that these simple corrections are possible only when the exposures remain in the 'straight-line' portion of the film-response curve.

A SIMPLE EXPERIMENT

An apparatus was constructed (Fig. 1) to test the utility of the method. A symmetrical wave pattern was generated in a circular tank (with a plate glass bottom) by tapping one side of the tank sharply so as to generate waves of equal amplitude but opposite phase on opposite sides of the tank. Uniform diffuse illumination was approximated by five equally-spaced photofloods shining on a white background. Although the illumination appeared uniform to the eye, the film, developed to extreme contrast and analyzed with a microdensitometer, showed marked variations in density from 0.82 at the center to 0.50 near the rim with some minor irregularities. The camera, a Ciroflex Model D, was mounted 38 inches above the water surface to obtain the maximum image size.

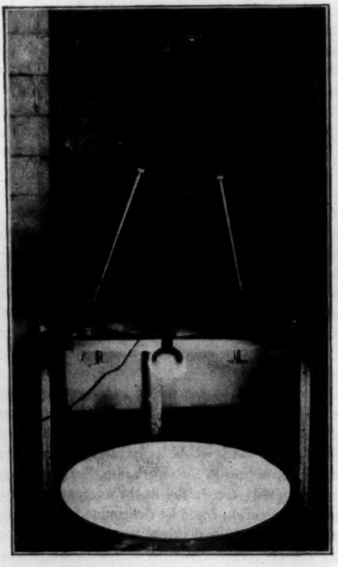

FIG. 1 – The experimental apparatus showing the circular tank with a glass bottom, illuminated from below and photographed from above

A means for calibrating the relationship of depth to density of the film was provided by the three leveling screws which supported the platform, tank, and tripod. By raising one of the supporting screws a linear variation of depth of fluid could be produced over any desired range from one side of the tank to the other.

Several black dyes were tested for spectral dependence of the absorption coefficient, and it was shown that for the conditions of the experiment (spectral film sensitivity, dye concentration and illumination spectra) water-soluble black nigrosine was sufficiently close to a uniformly black dye that the entire visible spectrum could be used with the assumption k_λ was equal to a constant.

The conditions of the experiment were as follows:

Dye concentration, water-soluble black nigrosine, 0.043 g/L.
Depth of solution, 1 inch
Diameter of tank, 18 inches
Relative illumination as measured by a GE DW68 exposure meter: before adding dye, 620; after adding dye, 13
Optical density of solution, 1.68; $\bar{k} = 4.03$ in^{-1}
Verichrome orthochromatic film developed 15 min at 23°C in D-19 developer
Duration of exposure, 1/200 sec
Lens aperture, f/5.6

The microdensitometer used for the analysis consisted of a microscope with a constant light source and a stop of 40 μ diameter. Light transmitted through this area of the film was received by a photocell and the output was displayed on the meter of an Ansco Color densitometer. Because of film granularity the meter fluctuated erratically by ± 0.05 as the film was transported continously across the optical system. For the wave analysis 1400 observations on a grid interval of 1 mm (image diameter 42 mm) were obtained.

Three photographs of the 'null' experiment were analyzed to obtain the illumination correction and to estimate variations of the shutter speed. The average film density was 0.70 and the difference between the lightest and the darkest points was 0.09. Measurements with the tank tilted from $z = 0.75$ on one side to $z = 1.25$ at the other gave a value of $\partial D/\partial z = -2.80$ in^{-1}. From (2) the approximate shutter speed variation may be determined

$$\frac{\partial D}{\partial t} = \frac{\gamma \log e}{t} = -\frac{1}{\bar{k}t}\frac{\partial D}{\partial z}$$

or for small finite differences

$$\Delta D = -(\Delta t/\bar{k}t)\Delta D/\Delta z$$

For the range of densities of 0.09 for the three trials the range of shutter speeds was 13.5 pct. A value of $\gamma = 1.6$ may also be obtained from the above value for $\partial D/\partial z$ uzing $\bar{k} = 4.03$ in^{-1} as determined approximately from exposure meter measurements. Much higher values of γ and greater sensitivity could be obtained by the selection of a special high contrast film.

Figure 2 is an analyzed wave pattern superimposed on a print of the wave photograph, the waves having been generated by tapping one side of the tank sharply. Contour heights are in terms of inches with a maximum variation from the average of ±0.1 in. The contour intervals are not quite constant because the contours were analyzed

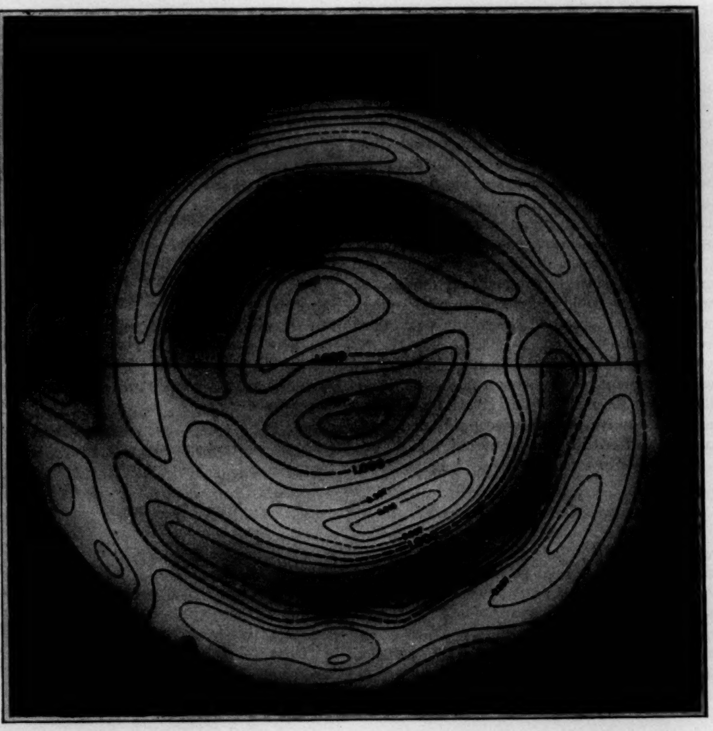

FIG. 2 – A microdensitometer contour analysis of waves superimposed upon the wave photograph; the contour interval is approximately 0.05 inch

on the basis of density and because the curve of the relationship of depth to density was not quite linear in this range of densities (approaching the toe of the film response curve).

The effect of the uneven illumination has been corrected in the contours by graphical subtraction of the 'null' density pattern from the pattern with waves. This effect is apparent in the print densities, however, which become darker (for the same contour height) nearer the rim. (Some error also is introduced in the superposition of the two patterns.) Small-scale irregularities are attributed to granularity of the film which led to erratic individual density values some of which have been smoothed out in the analysis. In defense of the method it should be added that no reference was made to the print of the wave pattern until the countour analysis had been completed.

CONCLUSIONS AND RECOMMENDATIONS

This optical method is suitable for obtaining the three-dimensional structure of a water surface, and rapid sequence photography can extend the technique to time variations. A complete record is obtained which may be analyzed selectively at a later date. Analysis of a large number of films could be accomplished by an automatic scanning device which could smooth fine-scale irregularities of the film and could apply a predetermined illumination correction automatically. Such a scanning system could be designed to produce the wave profile or spectrum along any particular direction.

Another technique for the analysis of the contours of constant density from a film is that developed by *O'Brien* and *Stewart* [1938]. By making successive positive and negative prints on Eastman Kodak Kodalith film an overall γ of 40 or more was obtained in which case a line of constant density appeared as a sharp boundary between black and white areas on the final negative. Different contours were selected by varying the exposure on the final positive Kodalith transparency. The principal difficulty in application to wave analysis would be the production of sufficiently uniform illumination that variations from this source would not contribute to significant density variations.

It is the author's opinion that by selecting a more suitable film, by producing more uniform illumination, and by smoothing of film irregularities an accuracy of better than one per cent of the total depth could readily be obtained, and that greater precision is possible under ideal conditions. Regardless of the accuracy of the method, a wave pattern photograph is obtained that is readily interpreted qualitatively.

Acknowledgment—The research reported in this paper was supported by the Office of Naval Research under Contract Nonr-1831(00)(NT 083-107), and was submitted in partial fulfillment of the requirements for the course Special Problems in Optics under the supervision of Arthur C. Hardy at the Massachusetts Institute of Technology.

GENERAL INFORMATION

On July 1, 1957 Beno Gutenberg retired as Director of the Seismological Laboratory and was succeeded by Frank Press. Beno Gutenberg remains a member of the staff. On February 5, 1958, Harry O. Wood, who founded the Seismological Laboratory, passed away after a long illness.

The long-standing condition of overcrowding at the Seismological Laboratory was corrected by the acquisition of an adjacent property. The new quarters, known as the Donnelley Laboratory, house offices for staff, visitors, and students as well as a library, map room, seismogram analysis room, and ultrasonic seismic model laboratory. An important feature of the Donnelley Laboratory is a tunnel 150 ft long, located in granite at a depth of 60 ft beneath the building. A linear strain seismograph and ultra long-period pendulums will be installed in the tunnel. The old quarters are being extensively remodeled and will be known as the Kresge Laboratory, housing the main seismograph vaults and recording rooms, experimental piers, electronics laboratory, machine shop, storage and stock rooms, photographic dark room, and offices for technicians.

STATION DEVELOPMENT

New station—San Nicolas Island, California (33° 14.9′N, 119° 31.4′W, h = 275 m) established July 24, with the support of the Office of Naval Research. Equipment: Benioff Z-component reluctance pendulum ($T_0 = 1.0$ sec.) with $T_g =$ 0.25 sec and 70 sec and one E-W torsion seismograph ($T_0 = 0.8$ sec).

Pasadena—Press-Ewing seismographs ($T_0 =$ 30 sec, $T_g = 90$ sec) discontinued operation at old seismological laboratory (now Kresge Laboratory) and installed with three components at the new Donnelley Laboratory near the end of September. Benioff reluctance Z component ($T_0 = 3$ sec, $T_g =$ 100, $Z_0 = 125000$ ohms; $C = 400$ mfd) transferred to Donnelley Laboratory.

Big Bear—Station discontinued September 20, 1957.

Hayfield—New housing occupied May 1, 1957. Benioff reluctance Z component seismograph ($T_0 = 1.0$ sec, $T_{g1} = 0.25$ sec). Second galvanometer ($T_{g2} = 70$ sec) added July 16, 1957.

Isabella—On September 10, 1957, torsion seismograph discontinued; ink-writing recorder for tidal strains and long period seismic waves installed on quartz extensometer; galvanometer with 600-sec period and displacement transducer installed on quartz extensometer for recording of long period seismic waves.

Palomar—Long-period ($T_g = 70$ sec) galvanometer added to Benioff reluctance Z-component seismograph December 10, 1957.

Dalton—Ink-writing recorder installed on quartz extensometer for recording tidal strains and long period seismic waves.

Additional instruments—Geomagnetic recording variometers ($T_g = 1.2$ sec) were installed as follows with the support of the Office of Ordnance Research, U. S. Army: Palomar, single photographic N-S component; Isabella, three-component photographic (N-S, E-W, and Z); Pasadena, single-component N-S heated stylus visible writing ($T_g = 0.5$ sec); Resolute Bay, Canada, single N-S component photographic, with the cooperation of the Department of Mines and Technical Surveys of Canada, and John H. Hodgson and P. L. Willmore.

INSTRUMENT DEVELOPMENT

Long-spread portable seismograph system (*Frank Press*)—In crustal exploration using reflected and refracted waves from explosive sources, it is important to have significantly larger distances between detectors than is customary. A system has been designed and used capable of providing records on a single oscillogram from six detectors spaced one km apart. This provides the necessary phase lag for identifying reflections, second arrival refractions, and determining apparent velocities of these events.

Strain recorder for long period waves (*Hugo Benioff*)—A galvanometer of 600-sec period is connected through a large capacitor to the carrier-current capacity-bridge transducer of the Isabella extensometer. The transducer output voltage is proportional to ground-particle velocity. The time constant of the network consisting of the coupling capacity and series resistances is four seconds. Hence, for the long-period waves of interest ($T >$ 30 sec) the voltage input to the galvanometer is proportional to the ground-particle acceleration and the resulting response of the galvanometer is nearly proportional to ground displacement for waves from about 30- to 600-sec period. These characteristics are particularly useful for mantle Rayleigh waves and G waves.

---

*Contribution No. 861, Division of the Geological Sciences, California Institute of Technology, Pasadena, California.

Ink-writing recorder for quartz extensometer (*Hugo Benioff*)—A new recording system having high sensitivity and excellent stability characteristics has been developed for recording tidal strains and long-period earthquake waves with the fused quartz extensometer. The system uses a fixed carrier frequency of five mc coupled to two resonant circuits having tuning capacitors formed by a plate attached to the end of the quartz tube and two fixed plates. The resonant circuits are coupled to crystal diode rectifiers whose output drives an Esterline Angus ink-writing recorder. Two forms are being tested. At Isabella the oscillator employs a vacuum tube. At Dalton the oscillator is driven by transistors and the rectified output current is coupled to a double push-pull transistor cathode-follower circuit devised by L. Blayney, which drives the Esterline Angus recorder. The all-transistor circuit version operates for several months on a set of dry cells and is thus entirely independent of the power line.

Experimental long-period pendulum (*Ralph Gilman*)—An experimental horizontal pendulum involving an electrical period lengthening device has been tried. The method makes use of an auxiliary transducer of the moving-coil type. A steady current is passed through the coils, poled in such a way as to produce a negative restoring force. Long-term pendulum stability has been achieved at an 85-sec period. Records have been made with a 90-sec galvanometer giving a peak response in the neighborhood of 60 sec.

NEW RESULTS FROM LONG-PERIOD SEISMOGRAPHS (HUGO BENIOFF AND FRANK PRESS)

The following long-period instruments have been in operation at the Seismological Laboratory for almost a year: (1) a modified Benioff vertical reluctance seismometer, $T_0 = 2$ sec, $T_g = 180$ sec, (more recently $T_g = 600$ sec); (2) Press-Ewing vertical and horizontal seismographs, $T_0 =$ 30 sec, $T_g = 90$ sec. For wave periods greater than several minutes the responses are approximately the same, whereas for waves shorter than 30 sec the response of the Benioff instrument falls off more rapidly because of the capacitor. Using both types of instruments the following results have been achieved: (1) mantle Rayleigh waves and G waves are recorded frequently from earthquakes with magnitudes as small as 6½–7; (2) the gap in the dispersion curve connecting crustal and mantle Rayleigh waves has been filled; (3) relatively long-period body wave pulses ($T \geq 30$ sec) are clearly observed owing to the reduced response to the shorter period, continuing earthquake motion; (4) the impulsive initiation of the Rayleigh waves corresponding to the components of maximum group velocity is now frequently observed with a characteristic appearance which serves to identify the wave group at sight.

VELOCITY OF SEISMIC WAVES IN THE EARTH'S MANTLE (BENO GUTENBERG)

The Earth's mantle may be divided into four regions: (a) from the Mohorovicic discontinuity down to a depth of about 200 km with small changes in the wave velocities which may have minima in this range; (b) from 200 to 950 ± km with relatively rapid, fairly regular increase in velocity without discontinuity; (c) from 950 to 2700 ± km with smaller and less regular increase in velocity; almost straight-line portions of the travel-time curves and relatively small wave amplitudes in certain ranges of distance indicate that at least in two portions of this region the wave velocities increase relatively little with depth; (d) from 2700 km depth to the core boundary with little change in velocity and possibly slight decrease approaching the core.

ATTENTUATION OF SEISMIC WAVES IN THE EARTH'S MANTLE (BENO GUTENBERG)

P and S waves with periods of less than a second near the epicenters are not observed at distances near 20°. In contrast, the period distribution of P and S does not change noticeably between distances of about 25 and 100° where P waves with components as short as one second exist, while S rarely has periods of less than four seconds. Waves at these distances have traveled mainly at depths below about 200 km in the mantle. In this portion of the mantle the absorption coefficient k for amplitudes of P, PP, and S is about 0.06 per 1000 km regardless of T, contrasting with results from laboratory experiments and from amplitude studies of surface waves which indicate that k is approximately proportional to $1/T$. Thus, attenuation processes in the mantle below about 200 km differ from those in the crust. The complicated structure in the lower crust and upper mantle prevents calculation of k for these.

SPECTRUM OF P AND S IN RECORDS OF DISTANT EARTHQUAKES (BENO GUTENBERG)

In records of shallow and deep teleseisms written at Pasadena simultaneously by various short and long-period instruments, body waves show distinct wavelets with relatively large amplitudes a. Their periods T usually differ appreciably on records of instruments with different characteristics. In P, a/T has maximum values at one or two different periods between one and seven seconds; maxima of a/T decrease for $T > 7\pm$ sec. Similarly, in PP, maxima of a/T decrease for $T > 12 \pm$ sec. In S, different instruments give about equal maxima for one to three periods between about 4 and 20 sec, maxima of a/T decrease for $T > 20$ sec. Neither P nor S show measurable dispersion. Contrary earlier findings have been based on records of a single instrument and probably result from combining data for different successive phases, including P, pP, sP, PcP and waves reflected or refracted at shallow discontinuities. Relatively long trains of P-waves with periods of one or two seconds occur frequently together with single wavelets of longer periods and may result from scattering as suggested by Tatel. For magnitude determinations, P-waves with $T > 10$ sec and S-waves with $T > 20$ sec should be avoided.

THE 'BOUNDARY' OF THE EARTH'S INNER CORE (BENO GUTENBERG)

Unlike P and S through the mantle, PKIKP-waves with periods of about one second arrive up to 20 sec earlier than corresponding wavelets with periods of over $5\pm$ sec. If this difference results from disperison in a transition zone between outer and inner core, the calculated 'radius' of the inner core is over 100 km greater for short-period than for long-period waves, and there is probably a rapid but not discontinuous increase in viscosity from the outer to the inner core.

THE AFTERSHOCK SEQUENCE OF THE KAMCHATKA EARTHQUAKE OF NOVEMBER 4, 1952 (MARKUS BÅTH AND HUGO BENIOFF)

Aftershock epicenters of the Kamchatka earthquake of November 4, 1952, are distributed over an area approximately 1030 km in length by 240 km in width. Assuming that this distribution represents the active strain zone, the total average strain, average elastic energy, and average stress of the rocks before slip were 11.9×10^{-6}, 1.35×10^{2} ergs/cm^3 and 12.6 kg/cm^2 respectively. The fault movement was transcurrent and dextral.

The strain release curve of the sequence has been constructed using observations from Uppsala and Kiruna. The curve exhibits three segments each of the form $J^{\frac{1}{2}} = A + B \log t$, where J is the energy and t is the time measured from the time of the principal earthquake. The slope B changes abruptly at $t = 0.4$ days and at $t = 195$ days, the latter change being particularly pronounced. Moreover, this was accompanied by other evidence suggesting a change in mechanism. The aftershock activity has its highest concentration in the vicinity of the principal earthquake and tapers off toward both ends of the active fault segment. The rate of strain accumulation and release for the time interval from 1897 to 1956 for the entire Kamchatka - northern Japan stress system shows a slow decrease with time. Comparison of the rate of the entire system with that of the aftershock sequence leads to an approximate estimate of the possible duration of the sequence of 15 years.

MECHANISMS OF THE AFTERSHOCKS OF THE KERN COUNTY, CALIFORNIA, EARTHQUAKE OF 1952 (MARKUS BÅTH AND C. F. RICHTER)

Using directions of first motion of P at nearby stations, the orientation of fault traces and the nature of fault motions have been deduced for 57 aftershocks. Unlike the main shock, they exhibit considerable strike slip, left-hand dominating on and to the south of the White Wolf fault, right-hand to the north of it. The two last mentioned mechanisms represent a secondary strain release, beginning not earlier than 37 hr after the main shock.

EFFECT OF UNEQUAL FLING OF TWO SURFACES OF A FAULT (HUGO BENIOFF)

When a fault is also the contact between two rock masses having unequal elastic coefficients or when the constraints on the two blocks are unequal as in the case of a shallow dipping fault, the radiation pattern departs from the symmetrical form commonly assumed in fault plane solutions. Considering compressional waves, the nodal plane which in the case of equal elastic coefficients coincides with the fault plane, is rotated toward the block with the larger elastic coefficient or with the greater restraint. The orthogonal relationship between this nodal plane and the one normal to the fault plane which holds for those faults with equal fling of the two surfaces is in this case no longer valid. Recordings made by John Healy with Press' ultrasonic model assembly show deviations of at least 15°. Since many earthquakes occur at or near the continental margins where the continental crust meets the thinner oceanic crust, some of the difficulties found in fault-plane work may arise from the departure from orthogonal condition.

CIRCUMPACIFIC TECTONICS (HUGO BENIOFF)

The evidence from seismology and geology as to the tectonic characteristics of the circumpacific margins suggests that there are two principal movements taking place. These are characterized by (1) a tangential slip parallel to the margin of the oceanic mass relative to the continental mass, and (2) a smaller relative radial movement of the two domains responsible for the pronounced marginal relief and some additional auxiliary faulting. The tangential movement is such that the continents are rotating in a clockwise direction relative to the oceans, thus producing dextral transcurrent faulting at the margins. The evidence from the South American segment is not complete so that these conclusions are necessarily tentative.

TABLE 1 – *Corrections for magnitudes as function of wave periods relative to those at the Seismological Laboratory, Pasadena, (negative corrections indicate calculated magnitudes larger than for Pasadena)*

Location[a]	Component	Period, seconds					
		0.2	0.4	0.6	0.8	1.0	1.2
Mt. Wilson	NS, EW	−0.2	−0.2	−0.2	−0.1	−0.1	−0.1

	EW	...	−0.2	−0.2	−0.2	−0.2	−0.2
Tinemaha	NS	...	−0.6	−0.6	−0.5	−0.5	−0.5
	EW	...	−0.5	−0.5	−0.5	−0.3	...
El Centro	NS	...	−1.0	−0.8	−0.6	−0.6	−0.6
	EW	...	−1.0	−0.7	−0.6	−0.5	−0.5

[a] The stations at Pasadena, on Mt. Wilson and at Riverside are on granitic rock, Santa Barbara is on alluvium with boulders, Haiwee on tuff, Tinemaha on basalt, La Jolla on beach deposits, El Centro on alluvium.

MAGNITUDE CORRECTIONS AS FUNCTION OF THE WAVE PERIOD FOR STATIONS OF THE PASADENA NETWORK (BENO GUTENBERG)

Magnitude corrections relative to the magnitude found at the Pasadena Seismological Laboratory on bedrock have been determined as function of the period for stations of the Pasadena network equipped with torsion seismographs (Table 1). For records of the strong-motion torsion seismographs at El Centro, measured on the 8× film projector, 1.35 was added to the logarithm of the amplitudes.

The 'average' correction for the Seismological Laboratory (probably +0.2 for waves having periods $T < 10\pm$ sec, 0.1 for waves with longer periods) has to be subtracted from all corrections in Table 1 to find 'average' magnitudes.

SEISMIC ACTIVITY IN 1957 (BENO GUTENBERG AND C. F. RICHTER)

In 1957 seismic activity increased from the low level during 1954 to 1956 to about average. There were at least 20 shallow shocks of magnitude 7 or more. Probably four of them, (March 9 in the Aleutian Islands; June 27, NE of Lake Baikal; July 28 in Mexico; December 4 in Mongolia) were great earthquakes ($m > 7.3$, $M > 7.7$) but none exceeded $m = 7.7$ or $M = 8\frac{1}{4}$. About five shocks of intermediate depth had magnitudes of 7 or more; two of them were possibly great, on November 29 in South America and on December 17 in the New Hebrides. Two deep shocks (depths 600 and 650± km) had magnitudes of 7 or more (about $m = 7.2$).

ENERGY RELEASE IN EARTHQUAKES (BENO GUTENBERG)

On the assumption that the energy E of a shock of magnitude m is given by

$$\log E = 5.8 + 2.4\, m$$

Table 2 gives annual energy releases (preliminary magnitude determinations for 1957).

TABLE 2 – *Annual energy release in 10^{24} ergs*

Year	Focal depth, km			
	<60	60–300	>300	all
Average 1908/57	6.0	1.6	0.3	7.9
1954	0.9	0.5	0.1	1.5
1955	1.3	0.8	0.1	2.3
1956	1.2	0.5	0.3	2.0
1957	6.0	0.9	0.3	7.1

Geophysical Investigation of Mono Basin (Frank Press)

In a joint project with the Geophysics Branch of the U. S. Geological Survey (L. C. Pakiser) seismic and gravity measurements were made in the Mono Basin, California. Seismic refractions indicated sedimentary depths as great as 5500 ft. An extrapolation to the center of the basin using gravity observations indicates a maximum thickness of about 12,500 ft. This great depression seems to have occurred along near vertical faults bounding a triangular block.

Phase-Velocity Method of Crustal Exploration (Frank Press)

In a joint project with M. Ewing of Columbia University a Rayleigh wave phase velocity investigation of the United States was completed. Crustal thickness determined by this method was 40–50 km in the Basin Range province, 42–49 km in the Rocky Mountain region, 35–41 km in the Interior Plains, 40 km under the Appalachian Mountains. The work made use of seismograms of the Pacific earthquake of April 14, 1957.

Model Seismology (Frank Press and John Healy)

An experimental and theoretical study of the relation between absorption coefficients for compressional, shear, and Rayleigh waves in low-loss media was carried out. A theoretical relationship was derived and experimentally verified. A two-dimensional experimental study of compressional and Rayleigh waves transmitted along a slit, particularly the conversion of these waves after passing into the homogeneous material beyond the slit was carried out. It was found that the Rayleigh wave is the predominant source of energy propagating into the medium beyond by a mechanism of Rayleigh to shear conversion at the end of the slit.

Sediment Thickness on Sea Floor (Frank Press)

A study of sediment thickness in the eastern Pacific Ocean (east and north of Easter Island) by the Rayleigh wave dispersion method yields values from 0.3–0.6 km with an average of 0.5 km.

Discussion of "The Columbus Geoid"

BY W. A. HEISKANEN

[*Trans.*, **38**, 841–848, 1957]

William M. Kaula (Army Map Service, Washington, D. C.)—The compilation of the Columbus Geoid has been a task of great magnitude and a valuable addition to our knowledge of the figure of the Earth. To extract the maximum benefit from gravity data for geoid computation, careful attention must be given in forming mean anomalies of areas both to the relationship of anomalies with topography, and to the correlation of anomalies with each other. The procedures used in computing the Columbus Geoid appear to take the topography into account very well, but the paper of Heiskanen is not explicit at some points where correlation of anomalies with each other is important:

(1) The method of estimating 1° square mean anomalies from the 5° × 5° maps is not precisely described.

(2) It is stated that maps of 1° square mean anomalies were used for interpolation and extrapolation of the gravity anomalies of the unsurveyed areas. If the coefficient of correlation used or implied in this extrapolation is incorrect, systematic distortions will result.

(3) The method of forming 5° square means from 1° square anomalies is not described. For 1° squares which have no observations, it is not stated whether zeros or extrapolated values are used, or whether they are entirely disregarded. Zeros will give 5° square mean anomalies systematically too small in absolute magnitude; disregard will cause the 5° means to be systematically too high.

(4) No mention is made as to whether any gravity data were rejected. It is hoped that none were (except for observational error), or, at least, that rejection criteria were not biased against any particular magnitudes.

(5) It is stated that the effect on ξ and η of areas beyond 3° has never been computed to be more than 4″, and of areas beyond 20°, never more than 2″. Considering how many areas have a mean anomaly assumed zero, these results are not surprising. With the present irregular coverage of gravity data, the only way accuracy of gravimetrically computed deflections can be estimated is indirectly, through the variance and covariance of gravity anomalies.

(6) It is stated that one observation cannot represent an area larger than 3° × 3°, and that zero is used for such areas. However, *Hirvonen* [1956] showed that the best value is the weighted mean of the observed anomaly and zero

$$\Delta g_s = \frac{G_s^2}{G_0^2}\Delta g_0$$

where G_s^2 is the variance of mean anomalies of squares of side length s, and G_0^2 is the variance of point anomalies. This rule applies to squares smaller than 3° × 3° as well, of course, and makes an appreciable difference down to less than 1° × 1°.

The use of spherical harmonics should not be condemned too hastily. Developments useful for such purposes as satellite perturbations should be obtainable from material already available, with proper techniques. Both *Jeffreys* [1941, 1943] and *Zhongolovich* [1952] committed errors which were not inherent in the harmonic method. Their principal mistake was in taking the 10° square mean anomalies to be the direct mean of those 1° square anomalies for which observed values were available. This procedure resulted in a pronounced correlation of the absolute magnitude of their 10° square mean anomalies with the number of observations on which they are based, as shown in Table 1.

The correlation is less marked for Zhongolovich's compilation than for Jeffreys', because Zhongolovich used all observations available within each 1° square, and because he omitted 25 10° square anomalies (without stating specific criteria for doing so).

Applying Hirvonen's weighting G_s^2/G_0^2, where $s = 10°/\sqrt{n}$, to Jeffreys' data reduces his rms 10° square anomaly to ± 16.3 mgal, and removes the correlation with n entirely; applying it to Zhongolovich's data reduces his rms to ± 13.0 mgal, but reverses the correlation for $n < 4$, indicating that his rejection criteria may have been biased against large magnitudes.

Zhongolovich's harmonic analysis also has questionable features in that (1) a third-degree

TABLE 1 – *Estimates of 10° square mean anomalies*

Number of 1° square values n	Jeffreys		Zhongolovich	
	Number of cases	Rms 10° square mean G_{10}°	Number of cases	Rms 10° square mean[a] G_{10}°
		mgal		mgal
1 to 14	149	±46.9	117	±26.9
15 to 30	38	40.6	34	26.4
31 to 60	31	24.3	35	20.6
61 to 100	3	19.4	18	16.5
1 to 100	221	±43.2	204	±25.1
Ratio of variances, $n \leqq 30/n > 30$	3.60		1.90	
One per cent significant ratio (Fisher z test)	1.99		1.76	

[a] Converted from Helmert to International Standard Gravity.

harmonic expression is used for the mean anomalies of 10° squares without observations, in computing the harmonics up to the eighth degree; and (2) all 10° square mean anomalies are weighted equally, to retain the convenience of orthogonality.

The Mapping and Charting Laboratory, Ohio State University, has issued a world map of mean free-air anomalies for 5° squares, dated December 28, 1956, which is presumably the basis for the Columbus Geoid. A total of 154 independent 10° square mean anomalies can be formed from blocks of four 5° square mean anomalies on this map. Applying the same analysis to these values shows a correlation with n in the opposite direction to Jeffreys' and Zhongolovich's as shown in Table 2.

These values raise a suspicion of either (1) too low a correlation coefficient in extrapolating 1° square mean anomalies; or (2) use of zeros for 1° squares in forming 5° square means; or (3) rejection criteria biased against large magnitudes. Note that Zhongolovich's ± 25.1/Heiskanen's ± 9.6 = 2.6, approximately the ratio by which Heiskanen states Zhongolovich's geoid undulations are "larger than the gravity observations permit."

TABLE 2 – *Estimates of 10° square mean anomalies*

Number of 1° square values n	Heiskanen	
	Number of cases	Rms 10° square mean G_{10}°
		mgal
1 to 14	23	±8.5
15 to 30	38	8.0
31 to 60	55	8.9
61 to 100	38	12.4
1 to 100	154	±9.6
Ratio of variances, $n > 60/n \leqq 60$	2.16	
One per cent significant ratio	1.79	

The Columbus Geoid is by far the best gravimetric geoid so far computed, and is a valuable guide for further developments. However, it not only must be regarded as a geoid of minimum undulations because of lack of data, but it also must be suspected of distortion; that is, of not being the most probable geoid on the basis of the available data. A more thorough harmonic and statistical analysis of the gravity field is needed before any major corrections of geodetic datums, etc., are made on the basis of gravimetrically computed geoid elements. In the past 25 years, there has been considerable development of techniques for analyzing stochastic processes, particularly stationary time series. Some of these techniques should be adaptable to analysis of the Earth's gravity field.

W. A. Heiskanen (Institute of Geodesy, Photogrammetry and Cartography, Ohio State University; author's closure)—I am indeed glad that Kaula has written his comments to my paper. Through positive critique we further science a great deal. Kaula obviously could only comment generally on our methods, because it has not been possible for us, because of circumstances beyond our control, to publish details concerning our gravity field.

The main subject of our discussion is how far and in what way we can extend the gravity anomaly field to the unsurveyed areas from the observed gravity values. Kaula has essentially six comments to make.

(1) This comment is based upon an incorrect impression. We have not estimated the 1° square

anomalies from the 5° × 5° maps. Quite on the contrary, the 1° × 1° square maps have been our basic maps.

(2) In the interpolation and extrapolation of the gravity anomalies of the unsurveyed areas we have used not only mathematical but also physical correlation. The correlation factors change a great deal from one area to another; so that, in our opinion, the mathematical 'advice' alone is not adequate.

(3) We have not estimated the anomalies of 3° × 3° squares from 1° square anomalies. For 1° squares without any observations we have used interpolated anomalies except in the case where the squares are too far from any observed point. How far we can extrapolate depends essentially on the large scale variation of topography of the area in question. For instance, we can extrapolate along the belts of negative gravity anomalies rather far but perpendicular to the belt we cannot. The gravity observations at the ocean islands cannot be extrapolated except to the island itself and its shallow 'apron.' The mean anomalies of 5° × 5° squares have been computed on basis of the observed, interpolated and extrapolated gravity anomalies.

(4) We have not rejected any gravity observations, except old and rather unreliable measurements where we have been able to replace them by modern accurate observations.

(6) I will consider (6) first, because it is closely connected with (1)–(4). I confess that in this case my wording is misleading. We have, in fact, used in addition to the physical evidence also the weight factors obtained by Hirvonen. We have, however, been careful with them, because they have of course been computed on basis of the material of the continents and we have to apply them mostly on the oceans where the G_s and G_o differ from their continent values.

(5) The effect of the areas beyond 3° and 20° on the vertical deflection components ξ and η, respectively less than 4″ and 2″, is based on our practical computations. In some cases the effect might be higher, but we can, by selecting the computation points carefully, avoid a great deal of the unfavorable areas. By the way, our results are in rather good agreement with Figure 6 of *Kaula* [1957, p. 304] which reveals that the "rms error of gravimetrically computed deflections of the vertical due to errors of representation of point anomalies plus lack of gravity data beyond given radii" is, beyond 3°, about 3.7″ and beyond 20°, 1.7″. When we had gravity observations also beyond both these boundaries, it is no wonder that our ξ and η values never exceeded 4″ and 2″.

We have one principal difference in our opinions. Kaula seems to trust the mathematical analysis 100 pct, while we use the combined evidence of mathematics and physics. I have in earlier discussions let nature itself testify whether the opinion of my opponent or my own is closer to the truth. I am sure also in this case that if we venture to extrapolate the free-air gravity values, which are not sufficiently representative for too large unsurveyed areas, like the South Pacific, nature itself cannot follow us. I have time to wait for two or three years when we shall have observations also from the now unsurveyed areas, and when the comments raised by Kaula will no longer have more than slight significance. Then we can see whether the undulations of the Columbus Geoid are too small or not.

We are about to develop gravity anomalies using low-order spherical harmonics. So far we have not had time, because, in our opinion, it has been far more important to try to obtain material and analyze it. Without this preparatory work no adequate applications of the gravity anomalies to geodetic purposes is possible.

We will publish soon a comprehensive investigation in which all our methods will be described in detail. A new "edition" of the Columbus Geoid, on basis of the increased and isostatically reduced gravity anomalies, will be published next winter.

As far as I remember in the history of geodesy, no less than three famous mathematicians have made mistakes when they, in writing about geodetic subjects, separated their analysis too far from the physical facts. One was about 80 years ago, one 30 years ago, and one ten years ago; in two of these cases nature supported my opinion. As to this case, we do not know yet which of us, Kaula or me, is closer to the truth. If I am right, it is good; if my good former student, Kaula, is right, it is not too bad either. At least one of my prophecies is right. I mentioned [*Heiskanen*, 1957, p. 7] that Kaula is "a man-of-the-future in geodesy."

Discussion of "Some Comments on the Results Obtained with the Cambridge Pendulum Apparatus in North America"

BY R. L. G. GILBERT

[*Trans.*, **38**, 457–461, 1957].

J. C. Dooley (Bureau of Mineral Resources, Geology and Geophysics, Melbourne, Australia)—The Cambridge pendulums were used in Australia by the Bureau of Mineral Resources, Geology and Geophysics during 1950–51. A statistical analysis has been made of the periods observed, and this will be published as part of a report on the survey. However, some of the conclusions reached are relevant to Gilbert's paper and to Garland's discussion.

In the Australian survey, six pendulums (1A, 1B, 1C, 6A, 6B and 6C) were used. Set 1 pendulums were used at Melbourne only; Set 6 were used at Melbourne and also at 58 field stations throughout Australia. A set of observations with one set of pendulums normally comprised two swings with pendulums A and B together, and two swings with pendulums A and C together. Six sets of observations were made at Melbourne with each set of pendulums, at intervals throughout the survey. A series of two or more swings with one pair of pendulums is referred to as a half-set of observations.

Analysis of the repeated observations leads to the following conclusions:

(1) The period of Pendulum A of either set varied according to whether it was swung with B or C, confirming *Cook's* [1954] observations.

(2) The variance of mean periods of a swing within a half-set was substantially less than would be expected from the variance of the individual periods of the pendulums. This indicates that motion of the support was an important factor, and that its effect on the periods was largely eliminated by taking the mean of two pendulums swung together.

(3) Pendulums 1C and 6C were generally more consistent than the average, and 1B was generally less consistent than the average. These differences in behavior were statistically significant in some groups of observations but not in all groups.

(4) The mean periods of Pendulums 1A-1C were significantly more consistent than the mean periods of other pairs of pendulums.

(5) The variance of individual periods of Set 6 for field work was generally not significantly greater than for base observations. There was no significant difference in the variance of the mean periods for field and base observations.

(6) The variance between the means of half-sets with different pendulum pairs was much greater than that estimated from the variance of means of swings. This was attributed to mechanical changes in the pendulums, or to magnetic effects.

(7) The repeated observations at Melbourne showed no systematic trend. The scatter of gravity values obtained was consistent with that estimated from the variance of means of half-sets.

(8) The difference between the periods of the pendulums of a set varied with time in a very erratic fashion. This appeared to be just as erratic for repeated observations at Melbourne as for field stations.

We agree with Garland that it would be unwise to rely on the results of one pendulum only. In particular, Pendulum 1B, which repeated best in the North American survey, was the worst in the Australian survey. It is not agreed that the adoption of an individual pendulum period is preferable to taking the mean period of a pair of pendulums swung simultaneously.

While it is true that comparison of the results of different pendulum pairs throws much light on the accuracy of the survey, it is agreed with Gilbert that repeated observations at a number of stations are highly desirable. Such observations afford the most direct means of investigating the mysteries of the behavior of pendulums, and lead to well established and accurate gravity values.

R. L. G. Gilbert (Dominion Observatory, Ottawa; Author's closure)—The problem of dealing with data such as is obtained from pendulum measurements is complex; as Garland points out in his discussion published with the paper, we should not neglect the results from four out of five pendulums without reasons. I am sure he would agree that the results might properly be weighted and combined. This raises a nice problem, however, in that it is debatable whether the 'jumps' in periods of the pendulums occur sufficiently frequently for a statistical method to be applicable, because, by definition, statistics deal with random errors, not discrete jumps. For the same reason, it is not certain that his claim, that Chauvenet's criterion indicates that no results should be rejected, is valid. I had certainly overlooked the fact that the results from pendulums of Set 1 and those of Set 6 can give an estimate of error at the stations. However, my assumption that Pendulum 1B is stable is by no means *a priori* in any sense of the expression; there is no evidence of instability at any of the stations at which more than one measurement was made, throughout both years of the survey, and it seems illogical to suppose that the pendulum should be unstable at intermediate stations. The main purpose of my paper was to point out that the method usually employed in reducing pendulum observations is not the only one which may be used. The difference in the final gravity values found using all the pendulums and only 1B shows that values at the various sites should not be regarded as having an accuracy better than about one milligal; I expect that a similar analysis on the Gulf pendulum records would lead to a similar conclusion. It may be noted that pendulum 1B gives gravity differences between Ottawa, Washington, and Teddington in good agreement with those quoted by *Cook* [1957] as the result of an analysis of many different measurements.

I was most interested in Dooley's contribution; in the case of the measurements at Melbourne, it would seem that ground movements were much more severe than in North America, and the errors from this cause will tend to obscure those from other causes, when individual pendulum periods are considered. His results confirm my tentative conclusion that Pendulum 1B did not perform well in other surveys.

The cause of the random changes in period may be caused by differential thermal expansion between the knife-edge and the body of the pendulum; a certain amount of elastic deformation could be tolerated, after which mechanical slipping would take place. This mechanism could easily explain the variation in behavior of pendulums during different surveys, with different operators, and it would be interesting to see if any improvement were to result from keeping the pendulums at as uniform a temperature as possible at all times during a survey including transit between stations.

The paper and discussions are primarily debating the best manner in which statistics may be used in the evaluation of the pendulum results. It is agreed that so long as ground movements are small, the period of a single pendulum may be used; this was generally true in North America, but seemingly not true in Australia. We have five independent sets of observations, made with apparatus which appears to suffer from random jumps in 'zero reading.' Elementary statistical analysis shows that in North America four of these sets of observations are subject to jumps and one is not; the order of magnitude of the jumps are one milligal, and the expected accuracy of an observation is about 0.3 milligal. The best method of using the results is debatable; if the jumps were an order of magnitude larger, the four sets of observations subject to jumps would be rejected on any grounds; statistical methods are not rigorously valid either for rejecting or for weighting the several sets of results, but it is clear that the sets of observations which are subject to jumps will have but little weight compared to the other. The only definite conclusions which can be drawn are that final results should not be adopted to closer than the nearest milligal, and that investigations are urgently needed to find the cause of the 'jumps' in the periods of the pendulums.

Discussion of "A Probe for Measurement of Thermal Conductivity of Frozen Soils in Place"

BY ARTHUR H. LACHENBRUCH

[*Trans.*, **38**, 691–697, 1957]

William Woodside (Division of Building Research, National Research Council, Ottawa, Canada)—The author has suggested a modification in probe design which he expects will enable the simultaneous determination of both thermal conductivity and thermal diffusivity. However, it appears that the thermal diffusivity may be estimated from data obtained with the present type of probe.

In the notation used in the paper, (1) with the time correction t_0 reads

$$\Theta(a, t) = \frac{q}{4\pi K}\left[\ln\frac{4\alpha}{\gamma a^2} + \ln(t + t_0)\right] \text{ for } t \gg \frac{a^2}{4\alpha} \qquad (9)$$

When $\ln(t + t_0) = 0$, let the value of the temperature rise be given by $\Theta(a, t) = \Theta_0$.

Then $\Theta_0 = (q/4\pi K)\ln(4\alpha/\gamma a^2)$ or

$$\alpha = \frac{\gamma a^2}{4}\exp\left(\frac{4\pi K}{q}\Theta_0\right) \qquad (10)$$

Since the values of $(4\pi K/q)$ and Θ_0 may be obtained from the corrected plot of temperature versus logarithm of time, the thermal diffusivity α of the test material may be evaluated, providing the value of a, the distance of the point of temperature measurement from the axis, is known for the probe in question ($\ln \gamma$ is Euler's constant which is 0.577). For the probe described, the value of a is probably known with fair accuracy. However, should the value of a not be known, it could be determined by inserting the probe in a material of known thermal diffusivity and performing a normal test.

The advantage of the above simple procedure for obtaining thermal diffusivity is that it may be applied to the data already obtained from the several hundred probe tests performed by the author, whereas the author's suggested modification to the probe design involves the repetition of these tests.

Arthur H. Lachenbruch (U. S. Geological Survey, Menlo Park, Calif., Author's closure)—I find two objections to Woodside's proposal. First, the equation given by him is valid, if at all, only for large t. In the present application this condition is not adequately fulfilled when $\ln(t + t_0) = 0$, and hence the equation cannot be used to represent Θ_0. We could, however, retain $\ln(t + t_0)$ and calculate the constant term using the observed value of temperature rise for say $t + t_0 = 1000$ sec. Even in this case however, we would not be justified in identifying the constant term with

$$(q/4\pi K)\ln(4\alpha/\gamma a^2)$$

because of the departure of the present probe from the mathematical model. This point constitutes the second objection.

As an illustration of the second point, consider the effect of contact resistance between the inner copper tube and the outer brass tube. Although the contact resistance at the outer probe surface can probably be neglected in this work, the effect at the interior interface is expected to be appreciable. By a slight modification of a result given by *Blackwell* [1954, Eq. 22] it can be shown that taking account of this effect changes the constant term to

$$(q/4\pi K)\ln(4\alpha/\gamma a^2) + (q/2\pi)(1/pH)$$

where p is the internal radius of the brass tube and H is the contact resistance. (Note that the correction term depends only on the properties of the probe.) The same effect leads to the following revised expression for ϵ (Eq. 7b of my paper) to the second term in η

$$\epsilon = -\eta[\ln\eta]\tfrac{1}{2}S - \eta[\tfrac{1}{2} + 0.10S] + \frac{a^2 c_0}{pH}\frac{1}{t} + \cdots \qquad (11)$$

Thus to this degree of approximation at least, t_0 is shifted by a constant amount independent of the test medium. If this contact resistance represented the only departure from the mathematical model, we could evaluate both α and H from a knowledge of t_0 and K by using the following two independent relations obtained from the large-time solution

$$t_0 \approx t_\epsilon \qquad (12)$$

$$\Theta \approx \frac{q}{4\pi K}\left[\ln\frac{4\alpha}{\gamma_a{}^2} + \frac{2K}{pH} + \ln(t + t_0)\right] \qquad (13)$$

where ϵ is modified to take account of H. Eq. (12) is applied in the manner described for (8), and in (13) we use the observed temperature rise corresponding to a large value of $t + t_0$. Alternatively we could determine H from a test in a medium of known diffusivity.

Analysis of the data reveals that at least one other important general departure from the mathematical model exists. This is probably the effect of low diffusivity in the insulating tubing.

There is another source of departure that might be expected in coarse-grained media that should be kept in mind in any refined interpretation of probe data. For early times, when appreciable amounts of heat have penetrated the medium only to distances on the order of the grain diameter, the aggregate will present a 'parallel thermal circuit' [*Birch* and *Clark*, 1940, p. 625] and a quite different effective thermal conductivity than that of the 'series-circuit' conductivity presented for large values of time. The latter is generally identified with the bulk thermal conductivity of an aggregate. With each added complication we can expect the labor required in determining the diffusivity to increase and the accuracy of the determination to decrease. A more detailed study of the present probe is planned in order that optimum use can be made of the many data obtained with it. However, I do not expect this probe design to yield diffusivities as reliable as those obtained by independent measurement of specific heat and bulk density. On the other hand, the theory provides a needed guide to the use of t_0 in determining conductivities.

Discussion of "The Statistical Treatment of Flood Flows"

BY P. A. P. MORAN

[*Trans.*, **38**, 519–523, 1957].

E. J. Gumbel (Columbia University, New York, received, Dec. 16, 1957)—Most statistical theories are based on the assumption that the observations are independent. In reality, most statistical observations are not independent. Still statistical methods continue to be used and often with a certain success. This may be because dependent observations follow statistical laws not too different from the independent ones. Therefore schemes developed for independent observations may under certain conditions also hold for dependent observations, especially if the dependence decreases with increasing distance between the ordered values. In the study of floods, the 365 daily observations during a year are not independent. The number of such observations is certainly less than 365.

Instead of the largest annual discharge, Moran uses the largest of the mean monthly observations. Thus, the number of observations from which the largest one is taken shrinks from 365 to 12. But this procedure does not result in independence, although the linkage between consecutive months may be weaker than that between consecutive days. In addition, the month with the largest mean may not be the month with the largest daily discharge. The procedure of taking the mean monthly discharge levels off the largest fluctuations. Therefore the safety of a structure which provides for this maximum may be insufficient.

We are not completely free in the choice of distributions to be used in a statistical analysis. The fact that we obtain a good fit, whatever this means, is a necessary but not sufficient criterion for the validity of such an hypothesis, since we can always devise formulas which will reproduce the observations exactly. However in such cases the formula takes its revenge for the constraint and the extrapolation may lead to fantastic results which nobody will accept.

Therefore *a priori* reasons are needed for the acceptance of a formula. Why should the distribution of the floods be logarithmically normal or of Pearson's type III? No *a priori* reason has been given by Moran and probably no such reason exists. The fact that the observed distribution is skewed to the left, a property of these two distributions, is not a sufficient reason since other such distributions exist. Behind the use of the lognormal distribution is hidden the assumption that first of all everything should be normal and second that if this does not hold every distribution can be reduced to the normal one by a logarithmic transformation, a statement which of course is erroneous.

By definition, floods are largest values. The distribution of largest values depends on the properties of the upper tail of the initial distribution of the discharges. The extremes are independent of the values occurring in the middle of the distribution and they are independent of each other except for the systematic climatic changes which may be neglected for the short intervals considered. The theory of extreme values as applied to the flood has a logical superiority: the floods are extremes. Therefore the asymptotic distributions of extreme values stand on a higher logical level in their use for floods than purely empirical procedures.

For the comparison between theory and observation Moran uses the χ^2 test. For a continuous variate this method requires two choices, the number of cells and the starting point of the division. The number of cells determines the numbers of degrees of freedom and this influence is known and can be eliminated. However the influence of the starting point is unknown and cannot be eliminated. In a previous paper [*Gumbel*, 1943] a numerical example has been shown where the probability $P(\chi^2)$ may vary from 0.02 to 0.70 according to the starting point chosen, and for the same observations, the same theory, the same values of the parameters and the same number of cells. To eliminate such catastrophes it is advisable to use the χ^2 test not for cells of equal differences of the variate but for cells of equal differences of probability. Then the starting point is fixed and its influence is eliminated. However, in its usual form, the χ^2 test is unreliable for a continuous variable.

GUMBEL, E. J., On the reliability of the classical chi square test, *Annals Math. Statistics*, **14**, 253-263, 1943.

G. N. Alexander (U. S. Geological Survey, Washington, D. C., received Jan. 31, 1958)—Hydrologists concerned with the application of statistical methods to the estimation of floods are indebted to the author for devoting his statistical talents to hydrology. This discussion will be concerned primarily with the methodology rather than the mathematics of the problem. We seek the most suitable mathematical model for answering questions concerning the frequency of occurrence of rare floods. Confusion of thought, referred to by the author, often arises because the questions have not been specifically framed. One obvious question is: What is the best estimate of the frequency (expressed in terms of probability or its reciprocal using a time scale, namely, the return period) of a flood of magnitude greater than U occurring during the life L of a dam, given n years of flood data?

The paper by the author helps to answer this question, by giving 'efficient' methods for fitting the log-normal and Pearson Type III curves to observed data, and showing methods of obtaining their confidence limits. This statistical procedure involves three steps: (1) selection of distribution type; (2) estimation of parameters from the observations; and (3) determining the error in the estimates by means of confidence limits.

It is not essential to follow this routine. We may dispense with the first step and estimate parameters graphically using an 'eye-fit', we may obtain distribution-free confidence limits which are independent of assumptions concerning the distribution type.

The usual justification for fitting a distribution to a set of observations is that better estimates of the parameters are obtained and extrapolation is facilitated. However, linearity in a sample as shown on a graphical relation between flood magnitude x and the return period T is no criterion for determining how well the sample represents the population. In such cases confidence limits are really more essential than where discontinuities or 'kinks' give a warning signal. Hence it is considered that the selection of distribution type which dominated the early discussions still occupies a place of undue importance in the problem as a whole. It is high time that the effect of sampling errors as indicated by confidence limits were better understood. Nevertheless some comments on type selection are in order.

Selection of distribution type—The author states: "the form of the distribution (of floods) is not known and must be guessed." This is true in an individual case owing to sampling errors masking the differences shown by different types. However as with other variables, examination of a sufficient number of independent samples helps in the selection of type and also indicates the range that the variance can take. Hydrologists often select the type from the appearance of the observed distributions of the samples on probability paper. Partly because of the availability of extreme value (Gumbel-Powell) and log-probability paper these two have been used in practice almost exclusively if a distribution is assumed. It would appear that probability paper could be constructed for testing graphically other distributions provided such a distribution has a constant skewness either using the original variate or one obtained by transformation. Since a relatively short record is available, a large error in skewness is common, and it is doubtful whether it is worth considering other types of distribution for floods, at least for practical purposes.

The writer endorses the *a priori* arguments summarized by the author against the acceptance of Gumbel's distribution for floods, but these arguments are not relevant if the distribution is judged by the preferred *a posteriori* criterion of goodness of fit. *A priori* arguments, based on the central limit theorem have been used by *Chow* [1954] to support the claims of the log-normal distribution. Again such arguments are not really relevant to finite samples. An analysis has been undertaken by *Beard* [1954] on the flood distribution of a large number of rivers in the United States based on data of the U. S. Geological Survey. This analysis suggests that in a high proportion of cases the distribution approaches the log-normal, with a mean skewness greater than that required by the Gumbel distribution. Fortunately the log-normal is mathematically more amenable than the Gumbel distribution and there is much to be said in its favor for flood flows.

Estimation of parameters—The author has made some categoric statements regarding the methods of estimating parameters, criticizing graphical methods because of their inefficiency and the ambiguity associated with the 'plotting position.' In view of the sampling errors, the efficiency of mathematical methods is more apparent than real, and graphical methods are often justified in practical applications on the grounds of expediency. Also, if no distribution is assumed, then parameters such as the estimated 50-year flood are only obtainable by graphical means.

As a modern statistician the author prefers the method of 'maximum likelihood' for parameter estimation. This may be more 'efficient' over the range of observations but the 'method of moments' by automatically weighting the upper values may have advantages particularly if a straight-line is fitted to facilitate extrapolation. It should be recognized that there is no absolute criterion for the selection of method of fitting.

The author states: "The correct method of fitting a log-normal distribution is to take the logarithms of the observations and use their observed mean and standard deviation as estimates of the distribution parameters." The meaning of this statement depends on the interpretation of the word 'correct.' Admittedly this method is the simplest and if we have a normal distribution (of the logarithms) conclusions dependent on normality are strictly valid. The above discussion on methods is however more of 'academic' interest than of practical importance because of sampling errors.

Confidence limits—The author employs the Neyman-Pearson concept of confidence intervals for the estimates of the 100-year and 1000-year floods. As this discussion concerns methodology it is pertinent to examine this process for rigor and convention. The process envisages repeated sampling from a population whose parameters are usually (but not necessarily) estimated from the observed sample. By this means a (fiducial) probability is obtained that a specified range or interval covers the 'true' value of the population from which the sample was drawn. Considered graphically, this value will lie within a band whose width at any assigned return period T is a function of the fiducial probability P_f, the sample size n, the sample standard deviation s of the annual floods, and the type of sampling distribution assumed for the T-year flood. Note that the distribution of the T-year flood is not necessarily the same as the distribution of the annual floods. T is any positive integer.

This concept is very useful to employ with hydrologic time series for we have only one sample of the population observed whose length n is virtually limited by the length of record. Attempts to reduce the sampling errors by effectively increasing n by introducing other samples run the risk of being wrecked on the Scylla of nonhomogeneity or the Charybdis of correlation.

Of particular interest in the construction of confidence limits is the effect of n. Theoretically as $n \rightarrow \infty$ the confidence interval $\rightarrow 0$, but the approach is fairly slow, the width being inversely proportional to $n^{1/2}$. Thus, if n were increased from 50 to 200 the band would still be half as wide, and if n were reduced from 50 to 25 it would be about 70 pct wider; wide enough to contain many of the 'kinks' that are often ascribed to a change in the regime.

It is the usual practice to locate the confidence interval by using the observed sample to centralize it. This however is best regarded as a convention, for there is nothing in the confidence limit model requiring it and intuition suggests that one sample is of little value in locating the band. The ambiguities, associated with the plotting position referred to by the author are no greater than those concerned with locating the confidence band. Conventions are sometimes desirable to give consistency to results, but estimates so obtained are relative and not absolute.

If we have no absolute criterion for locating the confidence band, it follows that we cannot make precise probability statements concerning the location of the 'true' value within the interval. This is not necessarily incompatible with the conviction that at some stage the frequency of a flood decreases as its magnitude increases; it merely says that we do not know at what stage this decrease in frequency commences.

The author has demonstrated a method for computing confidence limits for the log-normal and type III distributions. The procedure given for the log-normal is identical with that which could be used with a normal distribution except that a transformation is required to log-units at the outset and the analysis is completed with a re-transformation to the original units. As the author states the confidence limits so obtained imply that the distribution of the T-year flood is log-normal.

In deriving confidence limits for Type III, the author assumes in effect that the distribution of the T-year flood is normal, and obtains confidence intervals which, for T greater than 100, are only about half as great as those for the log-normal. It appears that the comparative narrowness of the confidence band of the floods for the Type III distribution is partly accounted for by the lower estimate of the true value given by the Type III.

It is clear from the formula that the width of the confidence band for the log-normal for a given confidence coefficient and return period is proportional to $s/n^{1/2}$. As s is measured by the slope of the graph ($\tan \theta$) on log-probability paper, the width of the confidence band measured horizontally (for given T) is independent of s.

A graphical comparison of the horizontal width of the confidence bands for the log-normal and Type III for a given T and confidence coefficient shows that the difference between the two widths is small.

This suggests the possibility of estimating 'distribution-free' confidence limits for the factor t in the equation $x = \bar{x} + t \cdot s$. This factor, termed the reduced variate by the statistician, and the frequency factor by the hydrologist, has a distribution known as the non-central t.

Extensive tables by *Resnikoff* and *Lieberman* [1957] of the non-central t have been recently published which considerably facilitate the practical determination of its confidence limits. Strictly their use has the same limitations as in the 'central' t-test; if the variable can be normalized as in the log-normal distribution, this requirement is met.

Beard [1955] gave a method for obtaining confidence limits (for the log-normal) which according to his closure, he believes to be more precise than the non-central t. However, it gives intervals much wider than those found by the author, whose results accord closely with those using the published non-central t tables.

Application—We now return to the questions asked at the beginning of this discussion: What is the probability of a flood of magnitude greater than U occurring during a period L, given n years of record.

Following the author's procedure we can obtain an estimate X say, of the L-year flood from a fitted distribution of the annual floods. Then using the confidence limit procedure 'in reverse' we can estimate the risk α, that is, $\frac{1}{2}(1 -$ confidence coefficient), associated with the half-interval $U - X$. Then α gives the risk, or fiducial probability, of the 'true' L-year flood being greater than U. This gives an answer, but may be regarded as an error of the third type, to use Kimball's phrase, as it is the right answer but not to the question asked. It should be noted that for given U, the value of α is dependent, inter alia, on n, and hence not obtainable by extrapolation of the fitted line which is independent of n. To answer the specific question, we have to consider the distribution of the return period.

The author has given in his Eq. (2) the density function for the random variable T, whose mean value is P^{-1}. (Note that in the notation of (2), which we follow below, P is the mean frequency associated with the upper tail, and n is any number, not necessarily the number of years of observation.)

The probability of T being *less* than n is by the compound probability law simply given by

$$\Pr(T < n) = 1 - \Pr(T > n) = 1 - (1 - P)^n \qquad (12)$$

In this connection we require the probability of the flood occurring in a period of L years. Hence, $n = L$. Also the floods greater than U can be regarded as belonging to a population of floods whose mean return period is L years and whose risk of occurrence is α. Hence, the appropriate value of P to use in (12), is that corresponding to a mean return period L, hence, $P = 1/L$ and we have

$$\Pr(T < L) = 1 - (1 - 1/L)^L = 1 - e^{-1} = 0.63. \qquad (13)$$

It is believed that this probability is independent of the risk α but the solution to the problem of their simultaneous distribution will be left to the author.

At the close of his paper, the author using nonparametric methods, gives the value of $n + 1$ as the estimated mean return period for floods greater than those observed. He then goes on to say, "We cannot obtain in this way statements involving probabilities less than $(n + 1)^{-1}$. However, it is a curious fact if the true distribution is a logarithmic-normal one we can extend this idea to make a similar exact probability statement about x corresponding to any level of probabilities."

This appears to put the log-normal in a unique position, but this is not so: if the true distribution is known we can make statements at any probability level. In conclusion, this discussion goes at times outside the domain of the author's paper in the hope that he will maintain his interest in this inviting field of statistical hydrology.

P. A. P. Moran (Dept. of Statistics, Australian National University, Canberra, Australia; Author's closure)—In reply to Gumbel, the purpose of the paper was to show that rather different distributions can fit the observed data equally well and give quite different estimates of the probabilities of given extreme values. The log-normal and Type-III distributions were chosen as examples for their ease of fitting and no assumption of normality, concealed or not, is made. Gumbel's distribution is harder to fit and is known, in the case of extremes from some distributions, not to fit unless astronomically large samples are used. The χ^2 test was not used dogmatically; simple inspection of Table 1 shows that both distributions used are good fits to the observations. The main point of the paper is to emphasize how uncertain estimates of flood probabilities are.

In reply to Alexander, one of the advantages of using statistical theory in fitting distributions is that it enables one to estimate the uncertainty in the parameters of the distribution. The method of fitting the log-normal distribution is 'correct' because the quantities used are jointly 'sufficient' estimators. The author does not admit the validity of any arguments based on 'fiducial' probability. Alexander's last statement about the log-normal is not correct. The log-normal distribution belongs to a small class of distributions for which it is possible to make probability statements of the particular kind considered at the end of the paper, without knowing the parameters of the distribution.

Discussion of "Water and Drainage in Semi-Arid Countries"

by Alfred Loehnberg

[*Trans.*, **38**, 501–510, 1957]

Raphael G. Kazmann (Stuttgart, Arkansas)—This paper is an excellent guide to water policy and seems to have a broader application than the author may have intended. If we define drought or aridity in terms of periods when demand exceeds supply, rather than in terms of minimum annual precipitation, the applicability of the author's remarks are greatly and legitimately extended. For all practical purposes droughts become economic problems rather than climatological: If the user can afford to pay for water, the water can be supplied. It is in suggesting a rational general procedure for producing water in the cheapest way by taking advantage of the geological environment, that the author has made a significant contribution.

The author's proposed method of procedure is sound engineering: Expend effort (and funds) in the direction of greatest ultimate return. However the assumption that agriculture is the best use for the water is open to argument. Recent authoritative evaluations of the utility of water have arrived at other conclusions. *Koenig* [1956, p. 328] of the Southwest Research Institute has stated:

> "I submit the proposition that the use of irrigation in the arid lands of the twentieth century is not an appropriate use of that valuable resource, water, but is an attempt to follow a historical precedent and increase the value of the land. Actually from the standpoint of water use, agriculture is a marginal use of water. In the United States the water that will support one worker in arid land agriculture will support about 60 workers in industry."

Moreover the author takes for granted that the engineering applicability of artificial recharge through wells is a fact. The problem of technique has been solved. But the engineering problem, how to accomplish artificial recharge cheaply enough for use by agriculture, still awaits a satisfactory answer. The situation is analogous to the problem of saline water conversion, it can be done, but it costs too much at present to be competitive even as regards water for most industrial or municipal purposes. Thus, at present at least, the assumption that large-scale artificial recharge will be practiced as part of a scheme to supply agricultural water in arid areas, is a somewhat questionable one.

These minor reservations should not overshadow the merit of the author's work. This paper is, I believe, the first one that the AGU has published which has placed flood control and drainage in proper perspective in the picture of water-resource development. It would be interesting and desirable, were other non-consumptive uses of water such as navigation, hydro-power, sewage disposal, and recreation, also evaluated and classified as to their roles in the overall picture of water utilization.

There is need for additional thinking along the lines pioneered by the author not only for 'semi-arid' areas but for all areas. Broad feasibility studies of water utilization, placing emphasis on the maximum consumptive use of water are presently lacking. New advances resulting from the intensive study of water have not been reflected in the approach to water resources development.

How many hydrologists realize, for example, the implications of the recent statement by *Rodebush* [1957, p. 7] that the free energy dissipated when fresh water in a river flows into the sea and loses its identity is equivalent to 1000 ft of head? It points to the distinct possibility that within 50 to 100 years the use of fresh water for the disposal of wastes will be uneconomic in many areas: possibly small amounts of sea water will be pumped inland and used as the vehicle for waste disposal while the fresh water is consumed.

Broad policy papers are urgently needed to tie in and interpret the volumes of stream flow, ground-water, hydrogeological, waste disposal, navigation, and other data now being amassed at an ever-increasing rate. The author is to be highly commended in having broken new ground in the theory of applied hydrology. Others should join him in developing the theory of co-ordinated and reasonable water-resource development.

Alfred Loehnberg (Instituto de Ciencia Aplicada, Cuidad Universitaria, México 20, D. F., Mexico; Author's closure)—In the United States the utility of water for irrigation may be in doubt in certain regions. Most other national territories, however, stretched over the arid girdle, do not possess alternative agricultural regions in a humid climate with high productivity and efficient transport facilities for their products. The arid countries bordering the middle seas, for example, must practice irrigation to feed their peoples because one half to four fifths of their territories do not obtain sufficient rain to sustain even one safe crop per year. To imagine a high degree of industrialization for the Sudan and Egypt without extensive (and improved) irrigation is impossible. Mexico's future industrialization will, to a considerable degree, be based on irrigated industrial crops on parts of the arid and semi-arid terrains, which comprise 82 pct of the country's area. Excess of water in some of the remaining rain-plagued portions of Mexico is so great, that it justifies long-distance water transportation for urban and agricultural use alike.

The utility of water for several claimants in the presence of limited resources cannot be decided on financial calculations alone, but will increasingly have to be co-determined by social evaluation [*Loehnberg*, 1958].

Artificial recharge through wells for agricultural purposes is already practiced and is gaining ground. Mekoroth, Israel's public water company, carries out the procedures on a considerable scale in the plain of Lydda. Recharge of wells with surplus from spring flows during the rainy season should prove economical almost anywhere. An increase in application will depend as much on water engineers and hydrologists, being capable of demonstrating and calculating the feasibility of recharge for irrigation under given circumstances, as on further progress being made in the rentability of recharge techniques.

Kazmann's proposal to intensify work on the theory of coordinated water-resource development has the author's full support.

Discussion of "Some Problems in Non-Artesian Ground-Water Flow"

BY P. WILH. WERNER

[*Trans.*, **38**, 511-518, 1957]

M. Maasland (Kansas River Projects, Bureau of Reclamation, McCook, Nebraska)—An interesting series of ground-water flow problems is considered in this paper. It is encouraging to note that not all investigators have lost an awareness of the value of the Dupuit-Forchheimer assumptions for the study of this type of problems.

Ever since the condemnation by *Muskat* [1937, pp. 303–318], the indiscriminate criticism of these assumptions has become quite general. Muskat ignores the more balanced review by *Dachler* [1936, pp. 27–32; 88–98] and asserts that the Dupuit-Forchheimer assumptions are invalid because they neglect the flow components in the vertical direction as well as variations of the horizontal velocity in the vertical plane, and because the errors so introduced cannot be bounded. Both criticisms are serious and valid for certain conditions, and more exact solutions for various problems will be helpful in delineating the applicability of these assumptions. The inconsistencies that have arisen are not due to the assumptions but rather to the fact that they have been used for solving problems to which they do not apply.

The hydraulics of wells placed in water-table aquifers has been extensively studied [*Zee* and others, 1955; *Nahrgang*, 1956; *Peterson*, 1955, *Schneebeli*, 1956] and it has been found that the Dupuit theory gives a reliable formula for the discharge and that it gives a fair description of the shape of the water table, except in the immediate vicinity of the pumping well. For the type of problems considered by Werner, a recent analysis by *Engelund* [1951, p. 20] indicates satisfactory agreement between results from the Dupuit and more exact theory. When applicable, the Dupuit-Forchheimer assumptions are particularly useful for the study of transient problems, as it would be very difficult to obtain analytical solutions for this type of problems for more comprehensive initial and boundary conditions.

Scheidegger [1957] expresses surprise when noting that the above assumptions are still widely used for engineering calculations and repeats the criticisms of *Muskat* [1937].

The engineer deals with a great variety of field problems and is seldom so optimistic as to imagine that the complexity of field conditions can be encompassed in a mathematical theory simple enough to be usable in his computations. The reason why he uses a simple theory is that it leads to results that are sufficiently accurate for the intended purpose.

In the following, the nature of the assumptions will be briefly outlined. Furthermore, a different definition will be proposed for the coefficient of recharge p which would seem more consistent with that used in current literature [for example, *Jacob*, 1943; *Engelund*, 1951]. Some difficulties encountered in using results derived from the linearized Boussinesq equation will be indicated.

According to the Dupuit assumptions we may write the following formula for approximately horizontally directed flow over a horizontal impermeable layer

$$q = -cz\,(\partial z/\partial x) \tag{19}$$

where

x = horizontal coordinate (dimension, L)
z = vertical coordinate (dimension, L)
c = hydraulic conductivity (dimensions, LT^{-1})
q = discharge (dimensions, L^2T^{-1}; when multiplied with the unit length in the direction perpendicular to the xz plane, the dimensions are L^3T^{-1})

Eq. (19) is derived on the assumption that the velocity component at the water table is a measure of the average horizontal velocity in the vertical cross section below the water table [see *Dachler*, 1936, for a useful discussion of (19) and (20)]. *Boussinesq* [1877] extended this assumption and applied it also to a moderately sloping impermeable layer and wrote

$$q = czI = cz\left(\alpha - \frac{\partial z}{\partial x}\right) \tag{20}$$

where α is the slope of the impermeable layer.

Note that the impermeable layer slopes downward with increasing x. Observe also that x is measured in the horizontal direction and that z is measured in the direction perpendicular to the horizontal but that the height z is measured from the sloping impermeable layer.

It is tacitly assumed that α is small. If the water table is parallel to the sloping impermeable layer, it follows from Figure 3 and Eq. (20) that $q_p = cz_0\alpha$. Consideration of the elementary problem of flow parallel to the impermeable layer shows that $q_p = ct \sin a$, in which t is the depth of the ground water measured in the direction perpendicular to the sloping impermeable bottom. As $t = z_0 \cos a$, we may write from the latter formula $q_p = cz_0 \sin a \cos a = \frac{1}{2} cz_0 \sin 2a$. Since for small values of a the sine doubles when a doubles, it follows that (20) will be very nearly correct for parallel flow if we put $\alpha = \sin a$. However, if we derive the gradient I using Eq. (20) from the detail of Figure 3, it follows that $\alpha = \tan a$. This difficulty arises because, by using the Dupuit assumptions, we do not calculate the flow parallel to the sloping impermeable layer, but rather the flow in the horizontal direction. It is therefore imperative that the application of all equations derived from (20) be restricted to problems involving small gradients of the impermeable layer in which case $\sin a \approx \tan a$. The formulas are not suited for the calculation of details other than the discharge and the height of the water table. The formulas derive their usefulness from the fact that these factors are of major importance in most engineering problems.

It is significant to note that Werner restricts the use of his equations and indicates that his formula (I.1.4) is valid subject to (I.1.5) being reasonably constant for various values of x.

Let us now differentiate (20) with regard to x, in which case we find:

$$\partial q/\partial x = c\alpha \frac{\partial z}{\partial x} - c\left[z \frac{\partial^2 z}{\partial x^2} + \left(\frac{\partial z}{\partial x}\right)^2 \right] \quad (21)$$

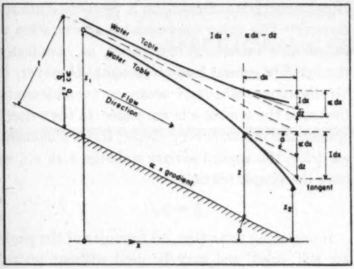

FIG. 3– Dupuit assumptions for flow over a moderately sloping impermeable layer

If there is a steady rate of replenishment p from the ground surface with which the water table is in static equilibrium, then $\partial q/\partial x = p$; since in this case q in (20) may be written as $q = p(x - a) + q_1$, in which a = the horizontal distance of the ground water divide from the z-axis, and q_1 is a component that depends on whether or not there is flow through the aquifer from one reservoir to the other (in Werner's terminology: 'original base flow'). Because of the nature of the Dupuit-Forchheimer assumptions we find that $q_1 = 0$ for $0 < a < L$, L being the width of the aquifer between the two reservoirs measured in the horizontal direction. If there is a constant rate of replenishment p with which the water table is not in static equilibrium, then $\partial q/\partial x = p - \epsilon(\partial z/\partial t)$, in which ϵ denotes the effective porosity. If these results are combined we obtain from (21) the following:

$$\frac{c}{\epsilon}\left[z \frac{\partial^2 z}{\partial x^2} + \left(\frac{\partial z}{\partial x}\right)^2 \right] - c\frac{\alpha}{\epsilon}\frac{\partial z}{\partial x} = \frac{\partial z}{\partial t} - \frac{p}{\epsilon} \quad (22)$$

which differs from (1) of Werner in that the last term is not p but p/ϵ. This is due to a difference in the definition of the factor p. As used here, it signifies the amount of surface applied recharge per unit area and per unit time, which definition is analogous to that of soil permeability. Werner defines (p/ϵ) as the speed of replenishment, and interprets it as a velocity of movement. However, the actual average velocity of movement of the water within the soil is a complicated function of the total porosity and the pore-size distribution, which function is not necessarily closely related to the effective or 'drainable' porosity. Apart from the fact that there is no apparent need to introduce a concept of dubious physical meaning, there is also the important consideration that for steady-state flow problems (constant p), knowledge of the effective porosity is not required. It would seem inadvisable to introduce factors in steady-state equations that are not relevant to the problem at hand.

Using the above definition of p, we find that the factor P in Werner's equations is equal to $2p/c$. Except for the change in P indicated, all his derivations and formulas remain unaltered because the division of the constant p by the constant ϵ does not change the nature of the basic differential equation.

Attention is also drawn to the fact that (I.2.7) should be corrected to read

$$p = \frac{c}{2} \cdot \alpha^2 \cdot \frac{2H_0D(e^{aL} - 1) - (H_L^2 - H_0^2)}{D^2(e^{aL} - 1 - aL)} \quad (23)$$

Note that the factor p as used in this formula signifies the rate of surface applied recharge and that the factor ϵ in the denominator is, therefore, lacking. Reference is made to the original article for an explanation of the symbols used. In the derivation of (I.2.7) the author erroneously associates the complementary function of the differential equation (8a) (the term z_1^2 of (I.2.3); that is, (I.1.3)) with a different value of D ($= D_0$ in Werner's notation) from the one used for the particular integral ($= D_m$). Although the complete solution is arrived at in a stepwise fashion, it is essentially a single solution for one (steady state) problem. There is no formal justification for separating any phases of the complete solution.

In deriving (8), Werner assumed that the variable z in (6) may be replaced by D, a weighted mean depth of the ground-water stream. In actual computations D is not known and a reasonable value must be chosen through some trials. If we make such trial computations with (II.2.6) for $p = 1.4 \times 10^{-4}$ m/day and for $D = 7.5$, 9, 10, 12, and 13 m, otherwise using the values given by Werner for his third example, we find that $z = 14.2$, 14.0, 14.0, 13.8, and 13.8 m, respectively. For $\alpha = 0$ we find from (II.2.7) that $z = 14.2$ m. It is observed that in this particular problem z (at $x = 0$) changes little even though D varies over a relatively wide range. *Dumm* [1954] gives a more detailed discussion of this aspect for formulas similar to those derived in the paper under discussion.

Formula (I.4.10) was derived earlier by *Jacob* [1943, 1944] for a water-table aquifer with large saturated thickness and was used to correlate ground-water levels with precipitation on Long Island, New York. There exists a special relationship between (6) of *Jacob* [1943] and (2) of *Dumm* [1954] (subsequently referred to as formula six and formula two, respectively) as evidenced by the following derivation. Let the rate of replenishment in formula six be r/t, where r is the amount of recharge during the interval t. From this slightly modified equation we immediately obtain the Fourier series of formula two for $t \rightarrow 0$ by applying l'Hopital's rule of limits. It thus follows that formula two is a special case of the problem treated by Werner and Jacob. Formula six may be said to describe the behavior of the water table in response to a 'step function' while formula two gives the fluctuation of the water table in response to an 'impulse,' that is, instantaneous recharge. It is beyond the scope of the present discussion to describe how these results may be used to analyze the behavior of the water table in response to consecutive recharges from repeated irrigations.

P. Wilh. Werner (Vattenbyggnadsbyran, 29, Humlegardsgatan, Stockholm 5, Sweden; Author's closure)—The writer expresses his appreciation of Maasland's interest in the paper, as manifested through his general line of thought. However, in his discussion Maasland seems to misunderstand the use of the symbol p in the paper. In the writer's opinion the matter is very simple. If, for a moment, we define the applied surface recharge with p_s, we have the simple relation

$$p = p_s/\epsilon$$

Introducing this value, all formulas of the paper are still valid, and may be used without restriction also for p_s.

This also applies when transforming (1) in the paper to (22), provided that the latter formula is corrected so that the last terms in its left-hand member reads $c\alpha/\epsilon \cdot \partial z/\partial x$ instead of $\alpha/\epsilon \cdot \partial z/\partial x$; note that the same error also appears in Maasland's Eq. (21).

In his numerical computations of the weighted mean depth D, Maasland assumes the value $p_e = 1.4 \times 10^{-4}$ m/day. However, as far as the writer is aware, the calculations refer to the value $p_e = 1.4 \times 10^{-3}$ m/day.

With reference to the last sentences in Maasland's discussion, it is worth noting that some of the formulas given in the paper give the clue to investigating the effect of consecutive recharges from repeated irrigations. This is also mentioned in the paper.

GEOPHYSICAL MONOGRAPH SERIES

Antarctica in the International Geophysical Year—Geophysical Monograph No. 1 (Publication No. 462, National Academy of Sciences—National Research Council), 133 pp. and large folded map of the Antarctic, 1956, 7" x 10" $6.00

Contains 16 separate papers by various American authorities on the Antarctic under the headings: General, Geographic and Meteorological, Geological and Structural, Upper Atmospheric Physics, and Flora and Fauna. Map (41" x 41") compiled by the American Geographical Society. Introduction by L. M. Gould, President of Carleton College and internationally recognized authority on the Antarctic.

Geophysics and the IGY—Geophysical Monograph No. 2 (Publication No. 590, National Academy of Sciences—National Research Council), 210 pp., just published, 7" x 10" $8.00

Contains 30 separate papers by leading American authorities under the headings: Upper Atmospheric Physics, The Lower Atmosphere and the Earth, and The Polar Regions. Preface by Joseph Kaplan, Chairman of the U. S. National Committee for the IGY.

Prices plus postage, unless payment accompanies order. Quantity discounts: 5–19 copies, 10%; 20–49 copies, 15%; 50 or more copies, 20%.

Reviews, Abstracts, and Bibliography

Reviews and Abstracts

ELIE CARAFOLI, *High-speed aerodynamics*, Pergamon Press, 710 pp., 1956, $15.00.

Carafoli's book is the English translation of the Roumanian volume Aerodinamica Vitezelor Mari. From his own work and that of others, he has attempted to provide the reader with a mathematical treatment of all aerodynamic problems which involve the compressible flow of air up to hypersonic speeds. Thus, the problems of subsonic wind tunnels, wings, and bodies are treated first, followed by similar treatments of the transonic and supersonic regimes. In 700 pages it is obviously impossible for him to go into great detail on any one subject with the result that the book abounds with mathematics and relatively little written text. The text is surprisingly clear and easy to follow.

Experimental data are used to a limited degree to illustrate various aspects of theory or physical phenomena. The subordination of experimental verification of theory requires the reader to be careful in accepting the material presented. Thus, while the findings are carefully qualified, the reader must extend his knowledge of a particular item by reference to other works.

The greatest value of this book appears to be as a reference for aerodynamicists, since most modern theories are collected in a single volume. It would be a convenient source of information on the theories of compressible flow for personnel in other fields who, on occasion, need aerodynamic theory in their work.

PHILIP DONELY

JOHN H. YOE AND HENRY J. KOCH, JR. (ed.) *Trace Analysis*, John Wiley and sons, xiii; 672 pp., 1957, $12.00.

This volume is the report of a Symposium on Trace Elements, sponsored by the Rockefeller Foundation and the Sloan-Kettering Institute, and held at the New York Academy of Medicine, November 2–4, 1955. It contains 24 chapters, with discussion, by authorities in each field, with emphasis on the theoretical background, sensitivity and applicability of each method, and practical uses. Although the major emphasis in the book is on biological applications, some of the sections include mention of geochemical work, and many of the methods are directly applicable to geochemical problems. Among these are *Chromatography* by H. H. Strain, *Ion exchange* by K. A. Kraus, *Spot tests* by Fritz Feigl and P. A. West, *Colorimetry* by M. G. Mellon, *Fluorometry* by C. E. White, *Flame spectrometry* by B. L. Valee, *Emission spectrochemical analysis* by L. W. Strock and R. L. Mitchell, *Mass spectroscopy* by M. G. Inghram, *X-ray spectroscopy* by Theodore Hall, and *Neutron-activation analysis* by A. A. Smales.

The book is highly recommended to anyone concerned with trace-element analysis, including both those making such analyses and those who wish to know their possibilities and limitations. Special praise is due the publishers for the fine job of printing and reproduction.

Notes and Personalia

Notes

VISITING LECTURER SOUGHT IN GEOPHYSICS—For the interval of March 15 to June 15, 1959, the University of Minnesota is in search of a recognized authority on most any phase of the broad aspects of geophysics, including exploration, preferably one who has an interest in geology or physics, or both. There is a substantial honorarium. Recommendations are solicited. Suggestions and recommendations should be sent to Harold M. Mooney, Chairman of the Department of Geophysics, University of Minnesota, Minneapolis 14, Minnesota.

TWENTY-FIRST INTERNATIONAL GEOLOGICAL CONGRESS—The Twenty-first International Congress will be held August 15–25, 1960, with headquarters in the building of the Mineralogical-Geological Museum of the University of Copenhagen in Denmark. The first circular is now available in the United States and Canada from the American Geological Institute, 2101 Constitution Avenue, N. W., Washington 25, D. C., and those in other countries should apply to their respective national offices or to the Organizing Committee at the Mineralogical Museum noted above. The American Geological Institute notes that all persons requesting the first circular will be placed on the mailing list to receive travel literature and other pertinent information.

POSTDOCTORAL FELLOWSHIPS OF THE NATIONAL SCIENCE FOUNDATION—The National Science Foundation has announced that these fellowships will be awarded annually in December as previously. Applications must be filed by October 15, 1958. Inquiries should be addressed to the Division of Scientific Personnel and Education, National Science Foundation, Washington 25, D. C.

FOREIGN FIELD RESEARCH PROGRAM—The National Academy of Sciences-National Research Council announces the availability of funds to support graduate level research work in areas outside the English-speaking areas of North America, not only for geographers but also for geomorphologists, climatologists, ecologists, pedologists, etc. Further information may be secured by writing to the Foreign Field Research Program, Division of Earth Sciences, 2101 Constitution Avenue, N. W., Washington 25, D. C.

FULBRIGHT AWARDS IN EUROPE, ASIA, AND AFRICA—Announcement has been made of university lecturships and advance research opportunities under the Fulbright Act in various countries of the Eastern Hemisphere. Interested persons should write to the Conference Board of the Associated Research Councils, Committee on International Exchange of Persons, 2101 Constitution Avenue, Washington 25, D. C. The closing date for applications is October 1.

COST OF RESEARCH AND DEVELOPMENT—A recent survey by the Bureau of Labor Statistics made for the National Science Foundation showed that the total expended on research and development in industry in 1956 was $6.5 billion, an increase of $2.8 billion since 1953. The Federal Government's expanding research and development program has contributed substantially to this, increasing 37 per cent in 1953 and to almost 50 per cent in 1956. Copies of this report entitled Reviews of Data on Research and Development, No. 10, May 1958, may be secured by writing to the National Science Foundation, Washington 25, D. C.

NEW MAP OF SAUDI ARABIA—A new map of Saudi Arabia sponsored by a number of groups has been published by the U. S. Geological Survey. The scale of the map is 1:2,000,000 on a sheet 48 x 55 inches and may be secured from the U. S. Geological Survey, Washington, D. C., at a price of $1.50. Copies may also be secured of the Arabic version from the Directorate General of Petroleum and Mineral Affairs, Jiddah and Ad Dammam, Saudi Arabia.

SCIENTIFIC PROCEEDINGS OF THE INTERNATIONAL ASSOCIATION OF METEOROLOGY—The Proceedings of the Tenth General Assembly held in Rome in September 1954 are available directly from the Association (R. C. Sutcliffe, Secretary, I.A.M.A.P., Meteorological Office, Victory House, Kingsway, London, W.C.2, England) at a price of 60 shillings. This volume contains some 100 scientific papers by authorities in various fields. Its former price was 80 shillings.

FALL MEETING OF URSI—The fall meeting of the

U. S. National Committee of the International Scientific Radio Union will be held at University Park, Pennsylvania, October 20–22, 1958. Interested persons should get into touch with the National Committee Office in care of the National Academy of Sciences-National Research Council, 2101 Constitution Avenue, N. W., Washington 25, D. C.

HEAT TRANSFER AND FLUID MECHANICS INSTITUTE—This Institute convened at the University of California at Berkeley, June 19–21, 1958. Its purposes are "to promote the preparation of, and provide facilities for the presentation of scientific and technical work of a fundamental nature in thermodynamics, fluid mechanics, and related fields of scientific endeavor." Sponsors of the Institute are California Institute of Technology, Stanford University, University of California, University of Santa Clara, University of Southern California, American Institute of Chemical Engineers, American Rocket Society, American Society of Mechanical Engineers, American Society of Refrigerating Engineers, and the Institute of the Aeronautical Sciences. The papers presented at the Institute were published in advance of the meeting by the Stanford University Press in a volume containing 264 pages.

EXTENSION OF HURRICANE OBSERVATION NETWORK—The U. S. Weather Bureau has announced the establishment of more than 100 new cooperative reporting substations in the hurricane-observing network, ranging from Eastport, Maine, to Brownsville, Texas. The cooperative hurricane stations are manned by unpaid volunteers and serve to supplement the full-time Weather Bureau stations already established. Each of the new stations has been equipped with specially designed wind speed and direction indicators, a barometer, and a rain gage, and ordinarily will make one set of observations each day but will report more frequently whenever a hurricane threatens.

Personalia

DETLEV W. BRONK, President of the National Academy of Sciences and of the Rockefeller Institute for Medical Research, has been renominated by President Eisenhower as a member of the National Science Board. He is now serving as Chairman of the Board.

CHARLES E. CARVER, JR., Research Associate at Woods Hole Oceanographic Institution, has accepted appointment as Associate Professor of Civil Engineering at the University of Massachusetts at Amherst and will undertake his new duties as of September 1, 1958.

VEN TE CHOW, Professor of Hydraulic Engineering, University of Illinois, is making a consultation and lecture tour around the world covering points in England, France, Belgium, Austria, Turkey, India, Thailand, Japan, and the Hawaiian Islands.

ROBERT E. DILS, Associate Professor of Water Resources at the University of Michigan, has taken up duties as Head of the Cooperative Watershed Management Unit established in the College of Forestry and Range Management at Colorado State University.

EARL G. DROESSLER of the National Science Foundation has recently been awarded an honorary Doctor of Science degree by Loras College, his Alma Mater. He has only recently left his duties in the Office of Science of the Department of Defense to serve as Program Director for Atmospheric Science in the National Science Foundation. This a newly established position resulting from the recommendations of the President's Committee on Weather Control and the Committee on Meteorology of the National Academy of Sciences-National Research Council.

ARTHUR W. HARRINGTON, District Engineer with the Water Resources Branch of the U. S. Geological Survey, with headquarters at Albany, New York, retired recently after more than 42 years of service.

JOHN B. HERSEY, jointly with Mrs. Hersey of the Woods Hole Oceanographic Institution, was recently awarded the John Fleming Medal of the American Institute of Geonomy and Natural Resources "for outstanding accomplishment in science and human welfare".

MYRON G. H. LIGDA, formerly Associate Professor of Meteorology at Texas A and M College, has taken up duties as Head of Radar Aerophysics Group of the Stanford Research Institute.

G. J. F. MACDONALD of the Department of Geology and Geophysics at the Massachusetts Institute of Technology has accepted an appointment as Professor of Geophysics at the Institute of Geophysics, University of California at Los Angeles.

HUGH ODISHAW, Director of the U. S. National Committee for the International Geophysical Year, has been awarded an honorary doctor's degree by Carleton College.

TROY L. PEWE Staff Geologist of the Alaskan Branch of the U. S. Geological Survey, and Associate Professor of Geology at the University of Alaska, has recently returned after spending a season in Antarctica in charge of a glacial party in the McMurdo Sound area making observations on Quaternary glacial chronology, permafrost, and polygonal ground.

DONALD A. RICE, Chief of the Gravity and Astronomy Branch of the Geodesy Division, U. S. Coast and Geodetic Survey, has been awarded the Colbert Medal for his "important contributions to the Department of Defense in the fields of gravimetric and topographic-isostatic reductions of the deflection of the vertical and of gravity."

PAUL B. SEARS, Chairman of the Conservation Program, Yale University, has been nominated by President Eisenhower as a member of the National Science Board. The nomination is now awaiting action by the Senate.

PAUL A. SIPLE, Biogeographer of the Research and Development Division, Office of Chief of Staff of the War Department, was recently awarded an honorary doctorate by Boston University.

ROBERT B. SOSMAN, Professor of Ceramics at Rutgers University, has received the Trinks Award, the highest honor of the industrial heating industry, for his pioneering research work in silica, steel-making refractories, and pyrometry.

ATHELSTAN SPILHAUS, Dean of the Institute of Technology, University of Minnesota, has resigned as a member from the United States of the UNESCO Executive Board.

Joseph E. Upson, Research Geologist with the U. S. Geological Survey, was recently given one of the nine Rockefeller Public Service Awards for his work in Holland with Dutch hydrologists on the methods of management of fresh-water resources along the coast.

Harold R. Wanless, Professor of Geology at the University of Illinois, has received a Fulbright Research Fellowship for nine months of work in Australia where he will study coal measures, carboniferous rocks, and ancient glaciation. He will also lecture at the University of Sydney.

Townsend Cromwell, Research Associate of the Scripps Institution of Oceanography and Senior Scientist with the Inter-American Tropical Tuna Commission in San Diego, was killed in an airplane crash on June 2 enroute to Acapulco to join the Scot Expedition aboard the research vessel *Spencer F. Baird.* He was born in Boston, Massachusetts, in 1922. He took his baccalaureate degree at the University of California in Los Angeles in 1947 after serving in the armed forces during the war period. He took his master's degree from the University of California at La Jolla in oceanography in 1949. He became a member of AGU in 1956.

Victor H. Jones of the Sedimentation Section of the Soil Conservation Service, Beltsville, Maryland, died March 6, 1958, at the age of 52. He was born in Sparta, Minnesota, took his baccalaureate degree from the University of Minnesota in 1926, his master's degree from the University of Iowa in 1928, and his doctorate from Iowa in 1933. During his graduate years he was Research Assistant at the University of Iowa and spent summers as Assistant Geologist with the Illinois State Geological Survey. In 1931 he took up duties as Assistant Professor of Geology at North Dakota State College and in 1934 and 1935 he was a Field Geologist with the Iowa Geological Survey. Since 1935 he had been associated with the Soil Conservation Service, chiefly on sedimentation studies. He became a member of the American Geophysical Union in 1943.

Union, Section, and Committee Activities

Minutes of Executive Committee Meeting, American Geophysical Union First Session, May 4, 1958

The meeting was called to order at 14h 00m in the Board Room of the National Academy of Sciences—National Research Council Building, 2101 Constitution Avenue, Washington, D. C., by Vice President Lloyd V. Berkner, who reported that President Maurice Ewing is recuperating from an operation at the Johns Hopkins University Hospital and had asked him to preside.

Present—P. H. Abelson, L. H. Adams, L. T. Aldrich, Werner A. Baum, Hugo Benioff, L. V. Berkner, Harry F. Blaney, Walter H. Bucher, J. J. Capello, Frank L. Culley, Earl G. Droessler, N. C. Gerson, H. H. Hess, Albert J Hoskinson, B. F. Howell, Jr., W. C. Jacobs, H. R. Joesting, J. W. Joyce, Joseph Kaplan, W. C. Krumbein, W. D. Lambert, H. E. Landsberg, Walter B. Langbein, John Lyman, Thomas F. Malone, J. H. Nelson, John A. O'Keefe, James A. Peoples, Jr., Charles Pierce, John C. Reed, A. N. Sayre, M. O. Schmidt, A. C. Simonpietri, Waldo E. Smith, Charles A. Whitten, and R. N. Wilson.

Approval of minutes—The minutes of the Executive Committee meeting held on October 25, 1957, published in the February 1958 issue of the *Transactions* (pp. 145–156), were approved.

General Secretary's Report

The last report of the General Secretary is recorded in the minutes of the Executive Committee meeting of October 25, 1957, published in the February 1958 issue of the *Transactions* (pp. 145–148).

Publications—The following issues of the *Transactions* have been printed and distributed since our last meeting:

- October 1957—188 numbered pages of text plus 20 unnumbered pages including 11½ pages of paid advertising; edition of 6200
- December 1957—205 numbered pages of text plus 15 unnumbered pages including 10 pages of paid advertising; edition of 6200
- February 1958—194 numbered pages of text plus 14 unnumbered pages including 8 pages of paid advertising; edition of 6400
- April 1958—190 numbered pages of text plus 18 unnumbered pages including 9 pages of paid advertising; edition of 6400

Through this interval we have continued to publish the *IGY Bulletin* in the closing pages of each issue, and the text proper aside from the *Bulletin* has been somewhat larger than we had anticipated. While the cost of printing the *IGY Bulletin* material is reimbursed by the U. S. National Committee for IGY, the larger number of regular text pages plus the increase in printing costs effective this year will cause us to exceed our current printing budget by a substantial amount, and recommendations will be made later concerning this matter.

The President's committee to study the problem of joining the *Transactions* with the *Journal of Geophysical Research* has pursued its work actively and will, I believe, make an important recommendation at this meeting for your consideration.

Advertising in the *Transactions* hit a peak in the August 1957 issue. On that occasion Chairman Gerson's Committee on Advertising made a special effort to secure as much additional advertising as possible, with the result that this issue contained 17¾ pages of paid advertising. The rates were increased beginning with that issue, but the one-shot ads for the August issue could not be counted on. Howland and Howland took over as our advertising representatives starting with the October issue at the new rate, and the total declined to a low of eight pages in February. The number of pages is nine in the April issue, and we are hopeful that this marks the beginning of a substantial increase. Anything that any of you can do (1) to secure advertising direct or (2) give us names of key persons in organizations that should advertise will be greatly appreciated.

Permission was given to the Microcard Foundation to manufacture and sell microcards of our *Transactions*. The original grant carried no provision for royalty, but the renewal made at the beginning of 1957 called for a ten per cent royalty, and the AGU has received a payment of about $123. In the future we should receive not only royalties from this source but also on the sales of the reprinted *Transactions* being undertaken by the Johnson Reprint Corporation.

The Editorial and Publication Committee has met regularly at bimonthly intervals to consider the many problems of the *Transactions*, including means for progressive improvement.

Plans have been completed for the publication of Geophysical Monograph No. 2 on the symposium on the IGY which was held in Washington at the time of the opening of the IGY last July. Some 30 papers will appear in this monograph, and it will run to about 200 pages. This will be handled on the same basis as Geophysical Monograph No. 1. We shall sell copies with the expectation of recovering the cost. But to the extent that this is not successful, the U. S. National Committee will purchase additional copies.

Application has been made to the National Science Foundation for $4000 to cover the cost of Geophysical Monograph No. 3.

The Russian translation project has been moving along exceedingly slowly, although Nos. 1 and 2 of *Izvestiia* (Geophysics Series) have now been released. This leaves ten numbers yet to be published. The quality of the translations of the first two numbers has been only fair and efforts are being made to improve the succeeding translations. The Special Board on the Russian Translation Project consisting of Perry Byerly (Chairman), Werner A. Baum, Walter B. Langbein, John Lyman, F. W. Reichelderfer, A. E. Scheidegger, Waldo E. Smith, and Victor Vacquier met on February 21 to consider these problems and recommended that the abstract journal based on translated abstracts from the Russian be discontinued because of the poor quality of the abstracts and their translations. We are now attempting to work out means to close up that phase of the project, both with Pergamon Press and with the National Science Foundation. It will involve setting up the project on a new basis, and negotiations are proceeding slowly. In this connection, representation is being made to the National Science Foundation for an appropriate overhead (preferably 15 pct) as recommended by the Executive Committee at its meeting on October 25, 1957.

Membership—Membership data as of April 21, 1958, are:

Membership as of October 16, 1957	5021	
Reactivated	6	
New Members, October 16, 1957 to April 21, 1958, including 69 applications now being processed toward membership	274	5301
Resigned	97	
Inactive	5	
Dropped 27; tentatively dropped 148 (see below)	175	
Deceased (reported since October 16, 1957)	16	293
Total April 21, 1958		5008

Dues unpaid—As of April 21, 1958, the following dues were unpaid:

Owe for 1958	605
Owe for part of 1958	12
Owe for 1957	181
Owe for part of 1957 and all of 1958	8

In addition, there are 148 persons who have not paid dues in full for 1956. According to the Statutes and By-Laws, these are hereby recommended to the Executive Committee to be dropped from membership, but with the usual added recommendation that one more effort be made to return them to active membership.

Deaths—The following 16 deaths have been reported to the office of the Union since our last meeting: Hyseyin Pektas, June 11, 1957; David W. Mann, July 2, 1957; Reginald A. Daly, September 19, 1957; E. Raymond Shepard, October 17, 1957; John C. Jensen, October 19, 1957; Richard C. Hubley, October 28, 1957; Robert T. Knapp, November 7, 1957; Howard E. Tatel, November 15, 1957; Henry C. Cortes, December 6, 1957; Elbridge C. Jacobs, December 12, 1957; Roy W. Goranson, December 25, 1957; Charles F. Brooks, January 8, 1958; Edmund Schulman, January 8, 1958; Henryk Arctowski, February 20, 1958; Peter H. Ottosen, March 31, 1958; Willis I. Milham, March 23, 1958.

Finances—Below is a brief statement of our assets as of April 1, 1958, in comparison with the last two years.

	Apr. 1, 1958	Apr. 1, 1957	Apr. 1, 1956
Cash balance	$39,402*	$32,732	$30,424
Permanent Fund	14,589[a]	13,741[a]	12,834[a]
Emergency Fund	1,000	1,000	1,000
T. M. and E. Award Fund	1,311	1,268	985
Russian Translation Fund	32,477	—	—
Totals	$88,779	$48,741	$45,243

* February issue of 1958 not yet paid, reducing this by $5500 to about $34,000.

[a] Does not include accumulated interest on $2368 of U. S. Savings Bonds. The total at this time of the year tends to give the wrong impression because most of our income for the year has been received and most of our expenditures are still ahead.

As noted above, our printing costs have gone up sharply this year, and it is now estimated that the

$24,000 budgeted a year ago will fall short of meeting requirements by about $7000.

It appears that under general office expenses most of the items are adequate, but salaries and social security appear now to be running about $2000 above the budget ($17,000 to $19,000), stationery and supplies about $500 ($1500 to $2000), and postage and communications about $200 ($1500 to $1700). The General Secretary has recommended to the Budget Committee that appropriate recommendations be made to you to cover these increases. Also our annual meetings cost somewhat more than the budget allowance, and an increase of $500 is indicated. Reprints likewise are apparently running over the budget amount, but this simply means that the income will also run over the budget amount and an increase from $2200 to $2500 in the cost means an increase of about twice that in receipts. Only a small part of the $500 set aside for equipment has been used. Sometime soon it will be necessary for us to replace our addressing equipment which will necessitate an outlay of $1000 or more, so we are attempting to hold the item down in anticipation of this contemplated expenditure. We will have a more detailed report on the current budget from the Budget Committee.

It is obvious that if we continue the publication of the *Transactions* on the present scale, an increase in dues of at least $1.00 and possibly $2.00 per year will be necessary beginning in 1959.

The financial statement for the year ending June 30 will be submitted to the Audit Committee as promptly as possible after the close of the fiscal year.

Office staff and jobs—It was not possible for Antioch College to supply us with a student during the current interval, and it is thus necessary to employ a fourth full-time staff member. The other full-time members are James J. Capello, Ethel G. Sanders, and Waldo E. Smith, Executive Secretary. In addition, Glenda Quinn Olmstead and Barry Modlin are continuing on a part-time basis as reported last October. We are in search of a clerk-typist to fill the fourth job.

Quarters—There has been no change in our present arrangements, and we continue to occupy five rooms in the building of the American Association for the Advancement of Science.

International matters—The Committee on International Participation met in New York on January 10. Chairman Joyce will make an extended report relative to the work of this Committee and the urgent need for a substantial revamping of the U. S. National Committee to make it a more effective instrument for carrying out its functions in AGU, the NAS-NRC, and the International Union of Geodesy and Geophysics. The recommended changes will involve changes in the governing board of AGU, that is, this Executive Committee. Changes have been urged upon us by the National Academy, and the need for these was underscored by the meeting in Toronto last September.

Meetings—The Pacific Northwest Regional Group held its meeting in Pullman, Washington, October 29–30, 1957. This was attended by the Executive Secretary, who subsequently proceeded to Seattle to clarify matters relating to the International Association of Oceanography in accordance with the instructions of the Executive Committee. The meeting in Pullman was a decided success and was attended by about 125.

The conference on Atmospheric Chemistry of the Compounds of Chlorine and Sulphur was held in Cincinnati, November 4–6, 1957, in cooperation with the U. S. Public Health Service and under the direction of Chairman James P. Lodge, Jr., of the Committee on Atmospheric Chemistry of our Section of Meteorology. The National Science Foundation made a grant of $4000 available chiefly to cover the cost of travel of foreign participants. The meeting was an outstanding success, and steps are now being taken to secure a grant of about $4000 more from the NSF to underwrite the publication of the results as Geophysical Monograph No. 3. To the extent that sales exceed costs, the fund, if received, will be returned to the NSF.

The AGU co-sponsored a session on December 30 on "Man and his environment, Part 1, Outdoor environment" at the AAAS meeting held in Indianapolis, December 26–30, 1957. At the coming meeting of AAAS, the Section on Agriculture has asked that we co-sponsor their symposium on water and agriculture. This invitation has been accepted.

The annual meeting of the Pacific Southwest Regional Group was held in Pasadena, February 6–7, 1958, with about 200 persons in attendance. The General Secretary had planned to attend this meeting, but was unable to do so, and none of the AGU officers was able to attend.

Plans for our annual meeting May 5–8, 1958, are complete, and the program is in your hands. It was decided to hold one session open (Tuesday afternoon) for late developments in IGY. N. C. Gerson, as Chairman of the Committee on AGU-IGY Relations, has arranged an interesting program for this session.

The Committee on Cloud Physics of the Section of Meteorology is hoping to hold another one of its successful conferences within the next year. It had hoped to do this in September 1958, but the time is now getting short. Approval has been received from the National Academy to apply for a grant to the National Science Foundation for $20,000 to hold the conference and another $10,000 to publish the results as a geophysical monograph.

Statutes and By-Laws—The ballot concerning certain changes in the Statutes was mailed out in December with the dues notices, and the ballots were tallied by the Committee of Tellers under the chairmanship of J. H. Nelson. The results of this ballot overwhelmingly favored all of the changes. Having also been approved by the National Academy, they are now in effect. The results appeared in the April 1958 issue of the *Transactions* (page 351).

American Geological Institute—Henry R. Joesting completed his second term as one of our representatives on the Board of Directors and James R. Balsley, Jr. was appointed in his place. Our representatives are now James R. Balsley, Jr., and Walter H. Bucher.

Nominating Committees—All of the Sections have now activated Nominating Committees in order to bring in nominees for the Section officers, and the Chairman of the Union's Committee on Nominations (L. H. Adams) has activated his Committee. We anticipate that nominations will be completed by late summer so that the meeting of the Executive Committee relative to these and other matters may be held in late September or early October 1958. One Section (Hydrology) has already reported its official nominees.

Miscellaneous—An overall meeting on abstracting and indexing in science was called by *Biological Abstracts* and held in Philadelphia, January 29-31, 1958, under the sponsorship of the National Science Foundation. This was a call to see what could be done with regard to science on a world-wide basis, and much enthusiasm was engendered for a voluntary federation to accomplish this job and to be sure that the entire field of science is adequately covered. It was pointed out that some 500,000 titles are covered currently by existing abstract journals, but the total is probably on the order of two million and to cover these adequately, including their indexing, will probably cost on the order of twenty million dollars a year. The meeting was attended by the Executive Secretary. In geophysics it was estimated that some 12,000 items a year should be covered, including those now covered by *Meteorological Abstracts* which total about 3000. The overall cost would probably be on the order of $120,000 to $130,000 per year. The AGU should indicate its willingness to take the lead in this and perhaps become a member of the newly organized National Federation of Scientific Abstracting and Indexing Services. In the absence of the President and the Vice President, the opportune meeting of the Board on the Russian Translation Project on February 21 and the fact that this project is concerned with the matter of Russian abstracts, Chairman Byerly of that Board appointed Werner A. Baum as Chairman of a subcommittee to study the problem for and on behalf of AGU.

The General Secretary attended the meeting of the Executive Committee, Office of Critical Tables, National Academy of Sciences, on February 3, 1958. We have recently received an invitation to name a representative on the Advisory Board of the Office of Critical Tables. President Ewing has requested Francis Birch to serve, but he is already on the Board. Suggestions are invited.

AGU forwarded its Annual Report for 1956-57 to the NAS-NRC in the late autumn of 1957.

The American Association for the Advancement of Science held a Parliament of Science at Washington, March 15-17, 1958, to consider the problem of education in science, which was attended by a representative group of over 100 American scientists and public leaders, including over 60 accredited observers. A number of AGU members took part in these deliberations, and a report of the conference was published in *Science*, April 18, 1958.

The AGU has received invitations to send representatives to a number of meetings during the last few months, among these being the Symposium on Natural Resources of Cuba, February 3-14 (Dr. Robert H. Randall and Dr. Andre C. Simonpietri were named as our representatives), and the meeting of the Pan American Institute of Geography and History held in Havana, February 12-22 (the following were designated: G. Medina, Chairman; Andre C. Simonpietri, Secretary; L. P. Disney, Albert J Hoskinson, David L. Mills, Leonard M. Murphy, George D. Whitmore, and Charles A. Whitten). Earl G. Droessler was designated as representative at the inauguration ceremony for the new Rector of Catholic University on April 16.

A. NELSON SAYRE,
General Secretary

Action on the General Secretary's report—The report was accepted.

Actions on matters relating to the General Secretary's report—The recommendation that the persons who have not paid dues in full for 1956 be dropped from membership after making one more effort to return them to active membership was accepted.

There was extensive discussion of the suggestion that AGU become a member of the newly organized National Federation of Scientific Abstracting and Indexing Service to be of assistance in implementing the abstracting and indexing of geophysical items. A motion was made and approved that AGU adhere to the National Federation of Scientific Abstracting and Indexing Service without financial commitment, and that $500 be appropriated from present funds for the Russian Translation Project to the new Federation if the National Science Foundation will approve this use of these funds. It was noted that a representative is to be designated. To study this problem, an *ad hoc* Committee consisting of John Lyman (Chairman), Werner A. Baum, J. W. Joyce, John C. Reed, and possibly one more, was designated. A motion was approved that AGU go on record as favoring the objective of a complete geophysical abstract journal which may be subdivided into sections involving specified units, but that this should be done without financial encroachment upon the regular funds of the Union. The thought was expressed that having the abstract journal in sections (such as the *Bulletin Signaletique*) would permit individuals to get the sections for their particular field.

Report for the President—In the absence of the President, Vice President Berkner noted that President Ewing had a feeling of great urgency with regard to matters pending for action, which actions he believed are important to strengthen the Union greatly, and that it is essential that we take some chances in the effort to improve the state of geophysics in the United States. Accordingly, the order of the agenda was suspended, and it was agreed that we should first hear the report of the Committee on Budget which had considered the problem under the status quo and that following this there should be a report of the Special Committee on Publications with subsequent further consideration of the budget report.

Budget Committee—Chairman John C. Reed presented a report indicating a deficit for the fiscal year ending June 30, 1958, of about $8250 and pointing out the need for further increased income to have a balanced budget. The report of the Committee was accepted, this not involving approval, and the Executive Committee went into brief executive session with regard to certain aspects of the budget problem.

Special Committee on Publications—Chairman James A. Peoples, Jr., presented the report published as Appendix 1. This, in essence, proposes dividing the *Transactions* into two parts. One would be a purely scientific and technological journal to be issued monthly, containing initially about 100 pages of papers per month well balanced across the broad field of geophysics and to be called *Research in Geophysics* or some other appropriate name. The notes and personalia, Union activities, and other material of a limited- or transient-interest or semi-popular nature would be published presumably on a quarterly basis, continuing the name *Transactions*. This endeavor, according to the budget tentatively drawn up, would result in a deficit of $16,000 or $17,000 a year. Thus a grant, say, of $50,000 for the first three years would be needed to put these journals on a permanent footing. The plan would be effective January 1, 1959.

The problem was broadly discussed. It was felt that the monthly journal with facilities for expansion should do a great deal to meet the greatly increased needs of geophysics and perhaps double the advertising potential of the journal. The Vice President cited a recent experiment in writing letters to 20 friends in high positions in corporations outlining the advantages of advertising in the AGU publications and of taking out corporation membership, feeling that if this experiment is successful other members should be urged to do likewise. Budget Chairman Reed pointed out that the budget deficit of $8000 in prospect on the status quo basis indicates the need for increasing dues or tapping some other sources of income. Kaplan stated that he felt that the quarterly publication containing semi-popular material might well provide authentic material needed by high school teachers and science writers, and that we should perhaps use some other title such as *Bulletin of American Geophysicists* or *Geophysics This Month* or *Geophysics in the Modern World* and use a sub-title "Formerly *Transactions* of the AGU," with a similar provision for expansion in this material to meet the increasing needs and possibly ultimately publishing it on a monthly basis. The amount of money that the National Science Foundation is spending to improve science teaching would justify serious effort on our part to help to meet this demand and somehow reach the professionally-minded teachers of science, although it was generally agreed that the primary responsibility of AGU is to publish a journal for professionals in geophysics that will be accorded world-wide respect. It was felt that a semi-popular publication should be handled as a separate or auxiliary project to the main project under consideration. It was noted that if the National Science Foundation chose to give support, they would prefer to subsidize a new journal, possibly including one that would publish IGY results.

The main effort will include the making of a serious personal effort to encourage those doing interesting work in geophysics to provide strong articles for this journal and improve its balance.

It is felt that a good case can be made for establishing a page charge levied against authors' institutions as suggested by Peoples' report (Appendix 1), but in no case would it be levied against the individual authors. This has worked out successfully for other journals. It was noted that the per-page charge probably would be quite essential to securing a grant from the National Science Foundation. It was also noted that the Controller General has ruled that page charges may be paid by Federal agencies.

A question was raised concerning the proposed payment to the editor of $500 per issue. The thought, expressed elsewhere, was repeated that we hope the editor would be a part-time individual (as someone put it, work half time for about one-quarter-time compensation) and that half of the amount would presumably be for secretarial assistance and the other half would be an honorarium.

It was pointed out that up through 1944, John A. Fleming as General Secretary acted in the capacity of editor-in-chief. While the Editorial and Publication Committee technique has been successful in raising the quality of the *Transactions* considerably in the interim period, there was a strong feeling that if a person of the right caliber can be secured, the editor-in-chief idea is perhaps preferable. It was felt that we should push hard to make the publications of AGU the top research journal in geophysics and that IGY results should provide a wealth of material for it.

A motion was made and approved adopting the report of the Special Committee on Publications (Appendix 1) from its beginning through the paragraph headed *Transactions* but not including Financial Matters, with instructions to the Committee to examine further the question of the title of the scientific journal as well as the modified *Transactions, AGU*.

A motion was made and approved adopting a page charge from authors' institutions in the United States and Canada which would entitle the accepters of this page charge to 100 reprints without further charge, this to go into effect with the new journal. It is understood that when an author's institution did not pay the page charge, this charge would be waived; however, the author would not receive free reprints. (Five voted in opposition.)

A motion was approved unanimously that the subscription rate should finally be set by the General Secretary, taking into consideration the recommendations of the Special Committee on Publications.

It was agreed that the successor to the *Transactions*, whether issued quarterly or more frequently and to include material of current interest, should be developed in accordance with the judgment of the officers with such assistance and advice as they may require.

It was further agreed that the Committee on Budget and the Special Committee on Publications should work together on the details of the plan approved to clarify the various questions raised concerning the financial matters in the report under Appendix 1, and that on the completion of the work of these two committees the budget for the fiscal year 1959 should be sent to the Executive Committee for mail ballot.

Reports of Standing Committees

Budget—A motion was passed approving the departures which the Committee recommended in its budget for the current year. This largely relates to the increases in cost (about $8000) in publication over that set forth in the budget published in the August 1957 issue of the *Transactions* (pp. 606–608).

A motion was made and approved that dues be raised from $8 to $10 for individual members beginning January 1, 1959, this being essential to meet budgetary requirements based on present operations. A motion was made and approved that students' dues ($3 per year) remain unchanged.

A motion was made and approved that the amount to be paid for life membership be increased from $150 (at present) to $200. (The By-Laws as amended to April 30, 1955, indicate that "Any Member or Associate, on payment of not less than $100 at any time, the amount to be fixed by the Executive Committee of the

Union, shall be relieved of further payment of dues." In 1956, the amount was placed at $150.)

Statutes and By-Laws—Walter B. Langbein, acting on behalf of Chairman K. Hilding Beij, made recommendations concerning the necessary changes in the Statutes and By-Laws to effectuate the changes in publications outlined in Appendix 1 and discussed above. The recommended changes, subject to modification with regard to titles of the publications, are set forth in Appendix 2. A motion of approval was passed. Notice is hereby given of the intent to change the By-Laws, and a ballot is to be sent out at an early date to the membership relating to the changes in the Statutes.

International Participation—Chairman J. W. Joyce submitted the report of the Committee given as Appendix 3 concerning the question of AGU representation at the International Union of Geodesy and Geophysics. Vice President Berkner noted that some changes are essential in order to make AGU more effective in discharging its responsibilities as the U. S. National Committee for the IUGG, that this matter should be discussed broadly among the members, and that any views developed should be conveyed to Chairman Joyce for inclusion in a further report for action by the Executive Committee at its fall meeting. He remarked that the relationship of AGU to IUGG is part and parcel of the life existence of AGU and must be retained, but there have been objections and criticisms from the National Academy of Sciences with respect to our present setup to meet these problems. Chairman Joyce noted that his Committee expects to work closely with the Committee on Statutes and By-Laws in recommending changes that seem to be appropriate.

It was further noted by Chairman Joyce that U. S. National Reports should be presented at each triennial meeting and that, if properly prepared, these should prove exceedingly useful to geophysics in the United States and would point out significant advances during successive three-year periods. We should attempt to eliminate dry factual presentations and encourage active and vital reports. A motion was made and approved that the National Report recommended by the Committee on International Participation be tried experimentally for the next General Assembly (four opposed).

Editorial and Publication—The General Secretary pointed out that this Committee has devoted a great deal of time and effort toward the improvement of the *Transactions*, editing papers, and excluding or condensing papers, and suggested that a resolution be passed commending the Committee on its zeal and high ability in carrying out its task. A motion was approved unanimously thanking the Editorial and Publication Committee for its continuing excellent work in the preparation of the *Transactions* and commending the Committee for the improvements made in format and contents which prepared the way for further expansion of the Union's publications.

In the absence of Chairman Perry Byerly of the Board on the Russian Translation Project, Werner A. Baum reported briefly concerning the activity of that Board, noting that it had met twice, February 21 and May 4, 1958. It is very much concerned with the slow development of the publication of the English edition of *Izvestiia* (Geophysics Series), noting that only Nos. 1 and 2 for 1957 have thus far been published and that the quality of the translations is not the best. He noted that the Board, at its meeting on May 4, met with I. R. Maxwell, President of Pergamon Press, and had received assurance that the translating difficulties have been largely overcome (there had been a turnover of 500 per cent in the translating personnel) and that Nos. 3, 4, and 5 should be issued in June 1958 and the other seven numbers by the end of August. The Board recommended that plans be laid for the continuance of the project for 1958, this to be with Pergamon Press only if a firm contract can be worked out bearing on problems of quality of translation and the appointment of suitable translation editors, a premium for early delivery and a penalty for late delivery, and the availability of funds from the National Science Foundation. If such negotiations cannot develop appropriately with Pergamon Press (assuming its commitments outlined above with respect to 1957 are fulfilled), then negotiations should be entered into with other companies with regard to *Izvestiia* for 1958. This recommendation was approved.

The Board also recommended that AGU seek funds from the National Science Foundation and, if available, negotiate a contract with some other translating publishers for the translation of *Trudy* of the Geophysical Institute of the Academy of Sciences of the USSR for 1958, using the same rules as suggested for *Izvestiia*. This was approved.

The Board also took cognizance of existing translations of books from the Russian and perhaps from other languages which have been made by United States agencies and which are not generally circulated at this time. It was also recommended by the Board that if we can assist the National Science Foundation in making these available through other than regular AGU funds, we should help to do so in every way possible. A motion was approved that the Executive Secretary, in consultation with the General Secretary and the Board, investigate this matter and initiate such a series if it appears appropriate and if support is available.

Nominations—Chairman L. H. Adams reported that initial steps have been taken looking towards a full report by late summer of 1958. All Sections were urged to have their reports complete by the middle of September, including biographies of candidates.

Meetings—Chairman P. H. Abelson reported that, in connection with arrangements for the Thirty-Ninth Annual Meeting, a few departures were made from past meetings, including a session devoted to IGY activity. He felt that the meetings next year should have a number of special sessions devoted to the IGY and its results. He noted that there has been favorable comment on plans for the dinner to be held in honor of the twentieth recipient of the William Bowie Medal, Prof. Johannes Theodoor Thijsse of The Netherlands, which will be attended by 45 or 50.

It was also noted that a regional meeting is to be held in Portland, Oregon, November 13–18, 1958, by the Pacific Northwest Regional Group at which Vice President Berkner plans to attend and address the group on some aspects of the IGY, a major theme of the meeting. The Pacific Southwest Regional Group will hold its meeting at Stanford University in January or February 1959.

The Committee on Cloud Physics of the Section of Meteorology held a highly successful conference in September 1955 and is laying plans for another conference to be held this fall, if possible. A request for funds has been made to the National Science Foundation to make this possible, including a reimbursable grant for publication of the conference proceedings as a monograph.

Membership—Chairman Earl G. Droessler reported briefly on developments since the meeting of October 25, 1957, and requested that members of the Executive Committee carefully look over the list of names of those about to be dropped for non-payment of dues and write to those whom they know to induce them to stay in the Union.

B. F. Howell, Jr., as Chairman of the Section on University Memberships, both students and faculty, reported briefly and noted that our student membership has grown substantially.

Reports of Special Committees

Relations of the AGU with the U. S. National Committee on IGY—Chairman N. C. Gerson reported that this Committee had organized a Symposium on Satellite Geophysical Studies for the afternoon of May 6 and stated that next year he would like to arrange three or four sessions in connection with the Annual Meeting relating to IGY activities. He noted further that he is maintaining touch with W. W. Atwood, Jr, relative to a joint venture whereby U. S. reports on IGY activities may be published through AGU, thinking that some of these at least might fit into our monograph series whereas others might be collections of contributions in various journals published in a given year.

Advertising—Chairman N. C. Gerson reported briefly, noting the recent effort by Vice President Berkner in writing 20 letters to friends in high positions in corporations relative to advertising. He noted further that the special effort of the Committee in connection with advertising in the August 1957 issue had been highly successful and that perhaps similar efforts should be made to increase advertising in the publications of the AGU on a permanent basis.

Geophysical and Geological Study of Continents—In the absence of Chairman George P. Woollard, it was noted that there was a brief report in hand relative to the work of this Committee. The report in full appeared in the June 1958 issue of the *Transactions*, pp. 492–496.

Resolutions—In the absence of Chairman John N. Adkins, a resolution was introduced and adopted expressing the Executive Committee's sympathy and hope for early recovery of President Ewing. The Executive Secretary was instructed to transmit this resolution by telegram.

Education—In the absence of Chairman John E. Nafe, it was noted that this Committee will meet on May 6.

Reports of Sections

Geodesy—President Milton O. Schmidt reported that there has been a broadening in the plan for annual programs by the Section of Geodesy that resulted in the holding of two sessions this year. John A. O'Keefe, Chairman of the Committee on Geodetic Applications of Artificial Satellites, reported briefly regarding two problems, namely, that the motion of the satellites is irregular partly because of tumbling and partly because of drag, and that celestial mechanics are now involved in geophysics. He noted that the first-order theory is not sufficient for the problems and that the second-order theory is very complex.

Seismology—Secretary James A. Peoples, Jr., reported that the Section is holding two sessions this year, both including excellent programs.

Meteorology—President H. E. Landsberg referred to the Conference on Atmospheric Chemistry of the Compounds of Chlorine and Sulphur held in Cincinnati in November 1957 in cooperation with the U. S. Public Health Service under the direction of Chairman James P. Lodge, Jr., of the Committee on Atmospheric Chemistry to the Section of Meteorology. It was noted that an application has been made to the National Science Foundation for a reimbursable grant of $3800 to underwrite the publication of the results of this conference as Geophysical Monograph No. 3. He further noted that the Committee on Cloud Physics of the Section of Meteorology is hoping to hold another conference within the next year. He mentioned that the AGU has been invited to be one of the cosponsors of a Symposium on Water and Agriculture to be held in connection with the AAAS meeting on December 29 and 30, 1958.

Geomagnetism and Aeronomy—The change in name of the Section was noted, and J. W. Joyce referred to the Symposium on Cosmic-Terrestrial Relationships to be held on May 6 as holding promise of being exceedingly outstanding.

National Research Council Reports

Physical Sciences—It was noted that L. T. Aldrich is now AGU representative in this Division.

Earth Sciences—Chairman H. H. Hess of the Division, who is our representative, reported on the successful conference on sea ice held by the Division in February 1958 and that a conference on drilling a hole through the crust of the Earth was held April 26, 1958. Frank Press has been designated to succeed Hess as AGU representative in the Division for the term starting July 1, 1958.

Affiliated Organizations

American Geological Institute—It was noted that a letter had been received from President J. V. Howell of the AGI indicating that something over 2400 members of AGU are not members of any other organization affiliated with AGI and suggesting that steps be taken that subscriptions for these persons may be covered by payment from AGU ($1200 suggested) or that these members be solicited for subscriptions and be dropped if they do not subscribe. The latter course seemed preferable to the Executive Committee as long as it did not drop these persons from the National Roster of Earth Scientists for which the AGI has responsibility. It was felt that most of these persons would not find it desirable to subscribe because the subject matter of geology covered by *GeoTimes* is largely outside of their interest. The matter was referred to the AGU representatives to make suitable recommendation to

President Ewing for reply to Howell. The further thought was expressed that AGU should take the responsibility for maintaining the roster of geophysicists and that perhaps there should be an affiliation of AGI with AGU.

American Association for the Advancement of Science—W. C. Krumbein, one of our two representatives on the Council of the AAAS, noted that our plans for the development of a program in connection with the AAAS meeting in Indianapolis last December did not develop because of the diversified character of that meeting.

Unfinished and New Business

Earl G. Droessler referred to a proposal made independently by Gerald J. Miatech and himself for the establishment of a suitable memorial in honor of the memory of James B. Macelwane, who at the time of his death was President of AGU. He suggested that AGU appoint an *ad hoc* committee to investigate this. With the consent of the Executive Committee, Droessler was asked to prepare a list of persons who might serve on such a committee and to make recommendations to the President as soon as possible.

With regard to the suggestion by S. F. Singer on the formation of a journal club in Washington to meet every two or three weeks, it was agreed that the AGU should encourage this endeavor, that it does not feel that as a national organization it can itself sponsor a purely local meeting, but that we will be glad to assist in offering moral support to the endeavor.

Attention was called to a proposal by A. J. Shneiderov that AGU sponsor a research project on paleomagnetism for support by the Office of Advanced Research of the Department of Defense. It was agreed that research activities, as such should not be undertaken by AGU and that this thought be conveyed to Shneiderov.

Reference was made to a proposal by a former member applying for readmission in the AGU on the basis that he be supplied with microcard copies of our publications instead of the publications themselves. A motion to authorize the Executive Secretary to put a note in the *Transactions* regarding this was lost.

Recess—The Executive Committee recessed at 18h 20m to resume its meeting immediately following the Business Meeting on May 7, 1958.

Second Session, May 7, 1958

The second session was called to order at 16h 45m by Vice President Berkner in the Auditorium of the National Academy of Sciences—National Research Council Building, 2101 Constitution Ave., N. W., Washington, D. C.

Present—Thirteen persons were present as follows: P. H. Abelson, L. H. Adams, Hugo Benioff, L. V. Berkner, J. J. Capello, Frank L. Culley, Earl G. Droessler, B. F. Howell, Jr., W. D. Lambert, J. A. Peoples, Jr., D. W. Pritchard, A. N. Sayre, and Waldo E. Smith.

L. H. Adams, Chairman of the Committee on Nominations, noted that under the rules adopted by the Executive Committee in the fall of 1946 preceding the first elections by mail ballot two nominees are required for each of the three elected officers of the Union and suggested that this requirement be made optional instead of mandatory. It was noted also that additional nominees may be added by petition of one per cent of the membership. Chairman Adams stated that it is sometimes advantageous to have two nominees for each office, but that from repeated experience on this Committee it is sometimes awkward and disadvantageous to find two nominees for each office. Secretary Howell of the Section of Tectonophysics noted that at the recent meeting of the Section it was agreed to eliminate the mandatory provision. Other Sections have likewise taken this step. After further discussion, a motion to refer this matter to the Committee on Statutes and By-Laws for study and recommendation to the Executive Committee for a vote by mail ballot was approved.

Adjournment—The meeting adjourned at 17h 05m.

A. Nelson Sayre, *General Secretary*
Waldo E. Smith, *Executive Secretary*

Appendix 1—Report of Special Committee on Publications*

Introduction—The International Geophysical Year has initiated a world-wide expansion of geophysical research, and recent developments clearly indicate that the present pace will continue or even expand with the official termination of the IGY. The geophysical journals as they exist today will not be able to publish all of the fine scientific reports which will surely result from this work.

The members of the American Geophysical Union need a larger and better balanced journal where the results of the geophysical investigations can be published promptly. Both the opportunity and the obligation are now apparent for the Union to assume its traditional role of bringing the various specialties together more effectively by establishing a scientific publication which covers all fields of geophysics including the expanding role of geophysics in space.

---

* Since May 4, 1958, when this report was submitted to the Executive Committee, there have been substantial and favorable developments toward the modified scientific journal. M. A. Tuve, Director of the Department of Terrestrial Magnetism of the Carnegie Institution of Washington, has lent his enthusiastic support to the project and agreed to combine the *Journal of Geophysical Research* with our publication. Conferences with the National Science Foundation have indicated endorsement of our endeavor and raised the expectation that our application for a substantial grant will receive favorable consideration. Finally, two distinguished geophysical scientists have indicated their willingness to act as co-editors-in-chief of the modified journal. It is now planned that each monthly issue will contain some 200 pages of scientific material of high quality.—Ed.

It is, therefore, recommended that the Union establish a new scientific journal which will be called *Research in Geophysics* (name subject to change—Ed.). It will take over the publication of scientific reports from the *Transactions* (name subject to change—Ed.) and seek a better balance of papers in the various fields *by expansion*. It is intended that the publication will be one which every geophysicist will want to read and in which he will be proud to publish. International interest, support, and membership will be solicited.

Editorial policy—The entire publication will be devoted strictly to serious scientific matters, plus advertising. It will consist of: (1) original research reports; (2) authoritative and critical reviews of the developments within or between the various fields of geophysics; the reviews will be published on a basis of timeliness and availability; (3) a *Letters* department will provide for: (a) quick but brief publication of unusual results; (b) brief discussion of previous papers; and (4) abstracts of papers given at Union meetings.

All fields of geophysics are to be included, and those papers or reviews which provide an insight into the interrelationships of the different fields are especially desirable. Papers are to be accepted on a basis of scientific merit regardless of the source.

The Editor, assisted by his Advisory Board, will have the responsibility of maintaining a high standard for the papers published. Papers submitted will be judged critically but fairly by referees selected for their competence to judge in the field of each paper. Every reasonable effort will be made to help authors of papers to meet acceptable requirements. Final decision on publication will rest with the Editor.

Parallel with the selection and editing of papers, there must be active solicitation of good papers, especially in those fields which have not been well covered in the past. It is recommended that a special committee including foreign representatives be appointed to assist in this.

Research in geophysics will be published twelve times per year beginning with the January 1959 issue (Vol. 1, No. 1). The number of papers per issue will depend upon the availability of suitable material and finances. The objective for the first year is 100 pages of scientific material per issue, plus advertising.

Advertising will not only provide significant financial support to the journal, but it will enhance the attractiveness and usefulness of the publication. The members of the Union are asked to assist in an aggressive campaign to solicit more advertising.

Format—The general appearance of *Research in Geophysics* must be compatible with the editorial policy. It shall be well planned, modern and dignified, but without frills. The problems of the reader and of the librarian in cataloging, printing, binding, etc., shall be given due consideration. The details shall be left to the Editor and his Advisory Board to work out.

Editors—The major responsibility for *Research in Geophysics* will rest on the shoulders of the Editor. He will have final authority in accepting or rejecting papers and advertising, and it will be his responsibility to establish and maintain an outstanding publication. Since this task will require a great deal of time and will require secretarial assistance, the Editor will receive an appropriate honorarium.

The Advisory Board will consist of sufficient mem-

TABLE 1 – *One issue of Research in Geophysics (100 pages of text plus 20 plates of advertising and miscellaneous material, total 124 pages)*

Receipts	
Page charges 60 pages at $15	$900
Advertising 12 pages at $200 (average)	2400
Dues $\frac{1}{2} \times 3 \times 5000$	1250
Sales and subscriptions $\frac{1}{12} \times 16 \times 750$	875
	$5425
Expenditures	
Printing 7000 copies at $30 per page	$3600
Cover	50
Mailing	200
Office work	1200
Editor	500
Direct advertising	600
Reprints	400
	$6550

Receipts	
Dues $\frac{1}{4} \times 1 \times 5000$	$1250
Sales and subscriptions $\frac{1}{4} \times 2 \times 750$	375
	$1625
Expenditures	
Printing 7000 copies at $30 per page	$600
Cover	25
Mailing	150
Office work and editing	300
	$1035

TABLE 3 – *Suggested annual Union budget covering Research in Geophysics (monthly) and Transactions (quarterly)*

Receipts	
Dues, 5000 members at $10	$50,000
24 corporation members at $100	2,400
Publications	
Sales and subscriptions 750×16	12,500
Advertising	28,800
Page charges	10,800
Interest	800
NRC Grant	400
	$105,200
Expenditures	
Research in Geophysics (12 × 6550)	$78,600
Transactions (4 × 1075)	4,300
General office	25,300
Expenses of meetings	1,500
Expenses of sections	100
Expenses of committees	100
Travel of officers	1,000
Directory reserve	1,500
Rent	3,700
President's fund	100
Contingencies	5,000
	$121,200

bers to represent the various specialties in geophysics. They will advise on general editorial policy and be responsible for refereeing the papers which are sent to them by the Editorial; they will be free to call on specialists to assist them in this work.

The Editor shall be appointed for an indefinite term by the Executive Committee. The Advisory Board shall be designated by the President in consultation with the Editor and the Executive Committee.

The Transactions—The *Transactions* shall be a regular periodical which contains reports of Union activities, notes and personalia, special announcements, and other material of a transitory or semi-popular nature. Initially it will be published on a quarterly basis.

Control of matter to be published in the *Transactions* shall rest in an Editorial and Publication Committee composed of one member from each Section designated by the Executive Committee of the Section. The General Secretary of the Union shall be *ex-officio* Chairman and the Executive Secretary shall be *ex-officio* Secretary. (Modified by approval of changes in Statutes and By-Laws; see Appendix 2—Ed.)

Financial matters (not adopted from this point onward—Ed.)—In order to finance *Research in Geophysics* and the *Transactions of the American Geophysical Union*, the following are recommended: (1) raise membership dues from $8.00 to $10.00 (Members would receive both publications); (2) solicit a fee of $15.00 per page from authors' institutions; no charge would be solicited for foreign contributions (except in Canada); no paper would be rejected solely because of inability to collect fee; (3) establish a subscription rate of $16.00 per year for both publications (in Table 1, taken as $14.00 per year for main journal, and in Table 2, $2.00 per year for the auxiliary journal); (4) solicit a grant of $50,000 to assist in the first three years of the publication; and (5) seek more advertising and more corporate memberships.

Tables 1 to 3 worked out by Waldo E. Smith and J. A. Peoples, Jr. are thought to be realistic estimates of the financial picture, if the above publication plan is adopted.

Table 3 indicates there may be a deficit of approximately $16,000 per year and it is for this reason that the securing of a grant is recommended.

J. A. Peoples, Jr., *Chairman*

Appendix 2—Suggested Amendments in Statutes and By-Laws to Implement the Peoples' Report

K. Hilding Beij, Chairman
Walter B. Langbein C. A. Whitten

Statutes

Article 1(b) To promote, coordinate, and facilitate the study of the various branches and interrelationships of geodesy and geophysics in the United States of America, its outlying territories, and the ocean; to provide for scientific discussion, publication, and dissemination of information relative to these fields through its publications.

Article 11: Publications—The official publications of the Union shall include the *Transactions of the American Geophysical Union*, *Research in Geophysics*, and the *Geophysical Monograph* series, published under the auspices of the National Academy of Sciences—National Research Council (titles subject to change—Ed.)

The *Transactions* shall be a regular periodical which contains the reports of Union activities, notes and personalia, special announcements, and other material of a transitory or semi-popular nature. Control of matter to be published in the *Transactions* shall rest in the Executive Secretary with the aid and counsel of the Secretaries of the several sections.

Research in Geophysics shall be a regular periodical which contains the scientific and technological papers and related departments. Control of matter published in *Research in Geophysics* shall rest in the Editor(s)-in-Chief appointed for an indefinite term by the Executive Committee. He shall have the aid and counsel of an advisory board representing the special fields of geophysics. This Board shall be designated by the President in consultation with the Editor(s)-in-Chief and the Executive Committee.

The *Geophysical Monograph* series will be published as members of the series develop and shall each be under the control of a special editorial board designated by the President, with the Executive Secretary serving as managing editor of the series.

Other publications that may develop shall be subject to approval by the Executive Committee under plans developed for their editorial management.

Non-members of the Union may subscribe to the *Transactions*, and purchase individual copies thereof, as well as other publications of the Union at rates approved by the Executive Committee of the Union.

Article 13(b) mentions *Transactions*, but there is no need to change.

By Laws

By-Law (2) Members of the Union, in classes (a) and (d) of Article 3 of the Statutes, shall pay dues, the amount for each year to be fixed by the Executive Committee of the Union. Members of class (e) shall pay dues of not less than $100 for each calendar year. Any Member or Associate, on payment of an amount to be fixed by the Executive Committee of the Union, shall be relieved of further payment of dues. Members of class (f) shall pay dues approximating the cost of a volume of the *Transactions* plus the cost of a volume of *Research in Geophysics*, the amount for each year to be fixed by the Executive Committee.

By-Law (3) Delete "Editorial and Publication."

By-Law (21) One copy of each issue of (a) the *Transactions*, (b) *Research in Geophysics*, (c) any published *List of Members and Officers*, and (d) any other publication which may be approved for free distribution to the membership by the Executive Committee of the Union, shall be sent to each Member, Associate, and Corporation Member whose annual dues for the calendar year have been paid by February 15; any person or organization newly elected as Member, Associate, or Corporation Member shall be sent without charge one copy of these publications beginning with the calendar year in which elected and for which dues have been paid. Each member on a retired basis, Member ex officio, and Corresponding Member shall be accorded this privilege also. Each Student Member shall receive one copy of each issue of the *Transactions* and one copy of each issue of *Research in Geophysics* for each year of paid membership.

Each person and organization in good standing in any class of membership may purchase any available publication of the Union at a discount from the printed price list to non-members. The General Secretary is authorized to establish discounts for sales of publications.

Appendix 3—Recommended Revision of the Structure of the Executive Committee of the American Geophysical Union to Provide More Effectively for Discharge of Responsibilities as the U. S. National Committee for the IUGG

(Not adopted; published as a basis for discussion—Ed.)

J. W. JOYCE, Chairman

LEASON H. ADAMS
LLOYD V. BERKNER
WALTER H. BUCHER
PERRY BYERLY
MAURICE EWING, *ex officio*
F. W. REICHELDERFER
A. NELSON SAYRE, *ex officio*
WALDO E. SMITH, *ex officio*

When first established under the National Academy of Sciences—National Research Council in 1919, the American Geophysical Union was designated as the U. S. National Committee for the International Union of Geodesy and Geophysics. The Executive Committee of the American Geophysical Union was to act as the Committee for Geophysics within the National Research Council.

At the time of its establishment, the total membership of the AGU was restricted to 65 persons. This limit was gradually increased until it had reached a hundred persons by 1929. In 1930 the limitation was completely removed and active efforts for increased membership began.

In order to meet operating expenses, including the support of an executive office and the publication of *Transactions of the American Geophysical Union*, annual dues are collected from individual members. These have been increased periodically in order to cover increasing costs as the activities of the AGU increased.

The prime function of the American Geophysical Union is to counteract the tendency toward specialization and is, therefore, diametrically opposed to that of societies serving individual fields. In so far as the AGU organizes meetings, collects dues, and issues publications, it has assumed, however, some aspects of a professional society.

The AGU's responsibility as the U. S. National Committee for the IUGG has continued in force but because of the increasingly large membership and the professional-society aspects of the Union the appropriate representational pattern as far as international matters are concerned has presented a problem. This may be subdivided into three parts:

(a) Now that several thousand persons are members of the American Geophysical Union, it is impossible to consider the entire roster as the U. S. National Committee as far as active participation of all individuals is concerned.

(b) It might be argued that the Executive Committee could serve as the IUGG National Committee, provided appropriate changes were made in the *Statutes and By-laws* as presently constituted. However, the procedures used to select the membership of the Executive Committee do not stress interest or experience in participating in international affairs, as exemplified by IUGG activities.

(c) Because certain agencies of the Federal Government are deeply concerned with geophysics, including the international aspects, it is essential that these agencies be represented on any body constituted to act as the U. S. National Committee for the IUGG.

These factors have resulted in having American delegations at IUGG General Assemblies who have been generally less prepared to deal with all the aspects of the various problems that arise at such a meeting when compared with delegations of certain other countries.

The need for effective representation at IUGG General Assemblies is becoming increasingly great. Experience has shown that many problems arise that are not necessarily of a pure scientific nature. These deal with matters of policy as far as the operations of the Union are concerned, matters of finance, or combinations of the two. Normally, questions of pure science do not present too great a problem. The importance of having effective representation will be particularly acute at the next General Assembly, now scheduled for Helsinki in 1960. This is due to very obvious moves on the part of certain countries to obtain as many elective officers as possible for their nationals, coupled with the fact that they will have large delegations in attendance.

The American Geophysical Union has discussed the need for more effective international representation over a period of several years, and in 1954 the Committee on International Participation, a standing committee of the AGU, was established to provide, as the name implies, recommendations and guidance for the strengthening of the position of the AGU in IUGG matters.

On January 10, 1958, several members of the Committee on International Participation met in the offices of the Associated Universities, Inc., at 10 Columbus Circle, New York City, to discuss what might be done to assure more active and effective participation of the American Geophysical Union in the international field that the AGU provides as a national, professional organization.

From the discussion that took place at this meeting there emerged a recommendation that the Executive Committee of the American Geophysical Union be reconstituted and renamed the Council of the American Geophysical Union. Briefly, the Council would be made up of the following:

(a) *Voting members*—(1) the elected officers of the AGU plus the Executive Secretary (four persons); (2) one member nominated by each section (this could be the section President or any other representative depending on the preference of the individual section) (eight persons); (3) one member nominated by each of the four government agencies having substantive interests in geophysics: Defense, Commerce, Interior, and the National Science Foundation (four persons); (4) four members-at-large nominated by the Section of Geophysics of the National Academy of Sciences (four persons); (5) U. S. officers to the IUGG or its Associations (variable number).

(b) *Ex-officio (non-voting) members*—(1) the chairmen of the various related divisions of the National Research Council (five persons); (2) the Director of the Office of International Relations, NAS-NRC (one person); (3) representatives from two government agencies having non-substantive interests in geophysics, Office of the Science Adviser, Department of State, and the President's Scientific Advisory Committee (two persons); (4) the chairmen of the various standing committees of the AGU (seven persons).

The names of all of the above persons would be placed in nomination to the NAS and their appointment would be made by the President of the Academy, as is now the case for the U. S. National Committee for URSI.

An Executive Committee would be selected from the Council to consist of three elected officers of the AGU and five members of the Council designated by the National Academy of Sciences from among the voting members of the Council. This Executive Committee would handle all but major policy decisions and could be brought together quickly and relatively inexpensively at times between the annual or semiannual meetings of the Council.

There is also a need to consider the AGU 'election cycle' in its relation to IUGG General Assemblies. Further, means must be considered for providing international experience and indoctrination to as many persons as practical. These are questions that will be given further study by the Committee on International Participation.

Prepared by:
Committee on International Participation
as a draft for consideration
by the Executive Committee, AGU

Special Announcements

NOTICE OF INTENT TO CHANGE THE BY-LAWS—Attention is called to the fact that at the meeting of the Executive Committee on May 4, 1958, initial steps were taken to amend the By-Laws as set forth in Appendix 2 of the minutes in this issue of the *Transactions*. In accordance with the statutes, notice is hereby given of the intent to change these. Subsequent action will presumably be taken in the fall meeting of the Executive Committee.

MEETING OF PACIFIC NORTHWEST REGIONAL GROUP—The Pacific Northwest Regional group will hold its Annual Meeting in Portland, Oregon, November 13–14, 1958, developing especially the theme of the International Geophysical Year. Interested persons should get into touch with the Chairman of the Regional Committee, Wilbur D. Simons, U. S. Geological Survey, 207 Federal Building, Tacoma 2, Washington.

MEETING OF THE *AAAS* IN WASHINGTON, D. C. DECEMBER 26–31, 1958—It is the plan that the AGU will join with the AAAS in this meeting, co-sponsoring various programs germane to geophysics, including one being arranged by the Section of Agriculture on the subject of water and agriculture, and sessions relating to the IGY.

PACIFIC SOUTHWEST REGIONAL MEETING TO BE HELD AT STANFORD UNIVERSITY, FEBRUARY 5–6, 1959—Plans are developing for the Pacific Southwest Regional meeting to be held at Stanford University. Interested persons should get into touch with Vito A. Vanoni, California Institute of Technology, Pasadena 4, California, or Joseph B. Franzini, Program Chairman, Civil Engineering Department, Stanford University, Stanford, California. It is the plan that at least hydrology, oceanography, and meteorology will be involved, and possibly other fields as well.

FORTIETH ANNUAL MEETING—The Fortieth Annual Meeting of the American Geophysical Union will be held in Washington, D. C., May 4–7, 1959, Monday through Thursday. This is the first call for titles and abstracts of papers and suggestions for symposia and other matters relating to the meeting. Send communications to P. H. Abelson, Chairman of the Committee on Meetings, 2801 Upton Street, N. W., Washington 8, D. C.; to the office of AGU, 1515 Massachusetts Avenue, N. W., Washington 5, D. C., or to the appropriate Section Secretaries or Program Chairmen as listed in the October 1957 issue of the *Transactions* pages 797–798.

IGY BULLETIN

A monthly survey by the U. S. National Committee for the International Geophysical Year. Established by and part of the National Academy of Sciences, the Committee is responsible for the U. S. International Geophysical Year program in which several hundred American scientists are participating and many public and private institutions are cooperating.

Preliminary Reports: Satellites 1958 Alpha and 1958 Gamma

Preliminary reports on data gathered by US-IGY satellites 1958 Alpha and 1958 Gamma were made to members of the National Academy of Sciences, the American Physical Society, and the Washington scientific community at a special meeting held May 1, 1958, at the National Academy of Sciences in Washington, D. C. The reports discussed high intensity radiation, micrometeorites, satellite temperatures, and atmospheric densities.

Observation of High Intensity Radiation

J. A. Van Allen of the State University of Iowa, on behalf of himself and his colleagues G. H. Ludwig, E. C. Ray and C. E. McIlwain, gave a preliminary report on radiation intensities measured with single Geiger tubes carried by satellites 1958 Alpha and 1958 Gamma.[1]

The counting rate of the Geiger tube in 1958 Alpha was transmitted continuously. Data were recorded only when the satellite was near one of the 16 receiving stations distributed over the earth (Table 1).

The data collected by 1958 Gamma were also telemetered continuously. In addition, a small magnetic tape recorder stored the data obtained during each entire orbit. Then, as the satellite passed near one of the receiving stations, a radio command from the ground caused these data to be read out.

A preliminary study of part of the data obtained from 1958 Alpha and from several interrogations of 1958 Gamma has been carried out, with the following results.

Reasonable cosmic ray counting rates have been obtained for altitudes below about 1000 km. In particular, a plot of intensity against height in the vicinity of California for the first two weeks in February, has been constructed. This curve, extrapolated down to altitudes previously reached by rockets, agrees with earlier data (Fig. 1).

At altitudes greater than about 1000 km, a very high intensity of radiation was encountered. This radiation was of such an intensity as to exceed the design capabilities of the electronic system for either direct transmission or for stored and played-back transmission. But the approximate magnitude of the intensity was determined by detailed study of the data and by laboratory calibration of the overall electronic system. It is estimated that for portions of the orbits of 1958 Alpha and 1958 Gamma, a Geiger tube of zero dead time would have been

producing over 35,000 counts/sec, or on the order of 1000 times the cosmic ray rate.

It is surmised that the newly discovered radiation is closely related to that previously found by the Iowa group above 50 km with rocket flights in the auroral zones.

Several important geophysical effects of this radiation are suggested. It is very likely closely related to auroras and geomagnetic storms. In addition, a rough calculation suggests that the radiation may be sufficiently intense to contribute important heating to the upper atmosphere. Also, the consequences in the production of atmospheric ionization, light, and radio noise are being investigated.

The directly observed effects in the satellite equipment are believed due to X-rays (bremsstrahlung) produced by the impact on the equipment of electrons of the interplanetary plasma which comes from the sun and encounters the environment of the earth.

Figure 2 exhibits a typical record of apparent counting rate against time obtained in an interrogation from San Diego at 1748 UT on the 28th of March. During the first 13 min (near perigee) the rate was well within the design capabilities of the system. Between 13 and 15 min the rate rose rapidly to exceed 128 counts/sec and remained above that value until 20 min had passed. Between 20 and 37 min the *apparent* counting rate was zero. This performance is interpreted as due to an equivalent rate exceeding 35,000 counts/sec (or 60 milliroentgens/hr of 80 kev X-rays)—i.e., a sufficient intensity of radiation to reduce the height of all Geiger tube pulses below the threshold level for triggering the scaling circuit. From 38 to 87 min the equivalent rate lay between 35,000 and 128 counts/sec, and again, near perigee of the orbit, from 87 to 107 min, the counting rate had the low value attributable to cosmic rays only.

A summary of counting rate data of this sort for several orbits of 1958 Gamma is given in Figure 3. Note that during the period March 28–31 the perigee was approximately at the most northerly latitude; hence, the altitude was low at high northerly latitudes and high at high southerly latitudes. Data from the continuous channels of 1958 Alpha and 1958 Gamma are concordant with each other and with data shown in Figure 3.

Preliminary interpretation of the data has been guided by the extensive knowledge which has been obtained by many rocket and balloon studies of the "soft radiation" in the

auroral zones. (See *IGY Bulletins* Nos. 3, 5, and 10.)

The satellite observations on which the present report is based are only a small portion of those available and now under systematic study.

Optical Studies

G. F. Schilling reported[2] on results from optical tracking of US satellites, based on work done by Charles A. Whitney, Theodore E. Sterne, and Luigi G. Jacchia at the Smithsonian Astrophysical Observatory. Preliminary analysis of the data obtained by visual observations and precise photographic observations has supplied information on the spin of 1958 Alpha, on air density at very high altitudes, and on the expected lifetime of 1958 Alpha.

Charles A. Whitney found[3] that 1958 Alpha, which was given a spin about its long axis during launching, now appears to rotate about its short axis, propeller-like. This conclusion is based on an observed variation of orbital acceleration.

Theodore E. Sterne has developed[4] a simplified formula for computing the air density at very high altitudes from the motion of artificial satellites. This formula, applied to orbital data inferred by Whitney through a critical study of visual and radio observations of 1958 Alpha, gives an air density value of about 1.5×10^{-14} gm/cm^3 at an altitude of 368 km. A cubic mile of air of this density would weigh only two ounces. Nevertheless, the density is about 15 times greater than that predicted in 1956 by R. A. Minzner and W. S. Ripley of the Air Force Cambridge Research Center.

Luigi G. Jacchia, using a formula developed by D. C. M. Leslie, and density values from the Smithsonian Interim Atmosphere of Sterne, Folkart, and Schilling, estimates[5] that 1958 Alpha will fall toward the end of 1962.

Orbital Determinations

Joseph W. Siry, of the Naval Research Laboratory, reported[6] that the effect of atmospheric drag on the orbit of 1958 Alpha has been difficult to predict due to the fact that the drag force depends so strongly upon the angle of attack in the case of a cylindrical satellite of large fineness ratio, such as 1958 Alpha. The orientation of the satellite as a function of time has been difficult to predict at times, thus making the prediction of the orbit correspondingly difficult. However, preliminary estimates by NRL indicate that the lifetime of 1958 Alpha will be about 5 to 10 years and that the atmospheric density in the neighborhood of perigee, at about 370 km, is approximately 10^{-14} gm/cm^3. This is an order of magnitude greater than the value predicted for this altitude in 1956 by Minzner and Ripley.

Temperature Measurements

A. R. Hibbs and E. P. Buwalda, of the California Institute of Technology Jet Propulsion Laboratory, reported[7] on a passive solution of space temperature problems and on temperature measurements made by 1958 Alpha. Internal temperatures ranged from 0°C to 35°C inside the cylinder and from 5°C to 40°C inside the nose cone. Shell temperatures ranging from −25°C to 75°C were recorded.

The temperature control mechanism consists of a series of aluminum oxide stripes covering approximately 25% of the outer surface of the cylindrical section of the instrument compartment, and 30% of the outer surface of the nose cone. By both reflecting and re-radiating heat received from the sun and the earth, this coating maintained interior temperatures within the range needed to protect instrumentation from damage by heat or cold.

The experiment was designed only to study the problem of controlling instrument environment in a very small enclosure. However, it was noted that this technique provided temperature control in a satellite within the range of human survival. With more elaborate techniques, available in a larger space vehicle, the inner temperature could be controlled within quite narrow limits at almost any desired level.

Micrometeorite Densities

Edward Manring, of the Air Force Cambridge Research Center, reported[8] on the determination of micrometeorite densities in the satellites' orbits by himself and Maurice Dubin.

Two micrometeorite detection systems are used. One, called the gauge detector, is carried on both 1958 Alpha and 1958 Gamma. The individual gauges are one cm^2 in area and are wound with two layers of enameled wire 17 microns in diameter. Twelve of these gauges, covering an area of two square inches, are mounted in a circular pattern flush with the surface of the satellite's mid-section. When a micrometeorite of 5- to 10-microns diameter and travelling at meteor velocities, on the order of 25,000 mph, smashes into one of the gauges, the continuous circuit breaks and changes the transmitted signal.

The second detector, flown only on 1958 Alpha, consists of a crystal microphone mounted against the skin of the satellite and connected to an amplifier. When the satellite is struck by a solid particle, the impact pressure is converted into an electrical signal which is transmitted to the monitor stations.

About 10% of the microphone data and 50% of the gauge data from 1958 Alpha are available for study. Seven hits have been detected by the microphone, but after 32 days of flight only one gauge had registered an impact. The data indicates that the average influx of particles 10 microns in diameter or greater was not more than $10^{-3}/m^2/sec$ during the period of observation, and that the average influx of particles four or more microns in diameter was about $10^{-2}/m^2/sec$.

Recapitulation

The above reports reflect preliminary results obtained from 1958 Alpha and, in the case of cosmic rays, from 1958 Gamma. Reports incorporating these preliminary results have now been sent to IGY World Data Centers and the Special Committee for the IGY. Analysis of the data from these satellites is continuing and will be the subject of further papers at an appropriate time.

There have been six satellites launched during the International Geophysical Year, three by the U. S. and three by the U.S.S.R.

The first USSR satellite, 1957 Alpha, is described in *Bulletin No. 5*; the second, 1958 Beta, is described in *Bulletin No. 6*. A report on 1958 Delta, the third USSR satellite, appears in the present issue of the *Bulletin*.

During the remainder of the US-IGY satellite program, satellite launchings will take place at the rate of about one a month, carrying a variety of experiments selected by USNC-IGY.

Third Soviet Satellite

The USSR launched its third artificial earth satellite, 1958 Delta, in the early morning of May 15, 1958. Following are selections from descriptive text issued on that date by Tass:

"In conformity with the program of the IGY a third artificial earth satellite was launched in the Soviet Union on May 15, 1958. The launching of the artificial satellite is intended for scientific research in the the upper layers of the atmosphere and cosmic space.

"The satellite entered its orbit inclined by 65 degrees to the plane of the equator. According to initial data, the greatest distance of the orbit from the surface of the earth is 1,880 kilometers [1168 mi]. The time of each revolution around the earth is 106 minutes. The satellite is separated from its carrier rocket which is following along a close orbit. . . .

"The third Soviet artificial earth satellite is conical in shape. The diameter of the base is 1.73 meters [5′8″] while its height is 3.57 meters [11′9″] not counting protruding aerials. The weight of the satellite is 1,327 kilograms [2925.5 lbs] including the weight of instruments for scientific research, radio measuring apparatus, and batteries weighing 968 kilograms [2134 lbs]."

Radio Moscow reported on May 15 that 1958 Delta ". . . carries equipment making it possible to carry out research along the entire orbit . . . [on] pressure and composition of the atmosphere in the upper layers; concentration of positive ions; the magnitude of the electrical charge of the satellite and the tension of the earth electrostatic field; tension of the magnetic field of the earth; intensity of the sun's corpuscular radiation; composition and variations of the primary cosmic radiation; distribution of photons and heavy nuclei in the cosmic rays; micrometeors; temperature inside and on the outside of the satellite."

Radio Moscow reported further that ". . . the satellite carries a multi-channel telemetric system with a high selectivity . . . [and] special transmitting installations which enable the carrying out of the measurements of the coordinates of its trajectory.

". . . it carries a transmitter continuously transmitting signals on 20.005 megacycles with a duration of 150–300 milliseconds and with a high power of transmission.

"The scientific and radio technical equipment installed in the satellite is controlled by a programming device. In addition to electrochemical sources of power, the satellite carries solar batteries. . . ."

On May 18, Pravda stated that the airtight satellite is made of aluminum alloys and is filled with gaseous nitrogen.

Radio signals from the satellite were first picked up abroad by the observatory of the University of Bonn, in Bonn, West Germany, at 6:15 am EDT, May 15, 1958. In this country the signals were first received by RCA Communications, Inc., at Riverhead, L.I., at 10:06 am EDT, May 15. First reception by a facility in the Naval Research Laboratory's Minitrack Network was at Woomera, Australia, at 8:35 am EDT, and, in this country, at the Ft. Stewart, Georgia, and Blossom Point, Maryland, Minitrack stations, both at 11:52 am EDT, May 15.

The first visual sighting of the satellite by a Moonwatch team in this country was reported by Robert C. Lehman, leader of the team at Harrisonburg, Virginia. Harvey Mast and Linford Gehman, members of this team, observed the satellite simultaneously at 9:03 pm EDT, May 15, 1958. The satellite was seen on its ninth revolution around the earth as an object of variable brightness, but of the first magnitude when at its brightest.

The first photograph of the satellite at a precision optical tracking station of the Smithsonian Astrophysical Observatory was taken by a Super Schmidt camera on Maui, Territory of Hawaii, at 0627 UT (2:27 am EDT), May 16, 1958.

Preliminary Report on the Thickness of Ice in Antarctica

The following report is based on material supplied by George P. Woollard, Department of Geology, University of Wisconsin.

Prior to the IGY, the only knowledge of the thickness of the Antarctic ice cap was obtained on the Norwegian-British-Swedish Expedition of 1949–52 to Queen Maud Land and on the earlier US expeditions led by Admiral Byrd. While the Byrd expedition measurements were all made in the vicinity of the Ross Ice Shelf, the Norwegian-British-Swedish expedition conducted a traverse from the sea ice onto the ice plateau, covering a distance of over 380 mi.

The feasibility of scientific over-snow traverse operations in the Antarctic was thus demonstrated; the results obtained constitute a milestone in the scientific exploration of Antarctica that ranks along with those of the Scott, Shackleton, Mawson, and Byrd expeditions. As a consequence, the US-IGY scientific program in Antarctica, along with that of other nations, includes seismic over-snow traverse operations as an integral component.

Information on ice thickness in Antarctica serves a number of scientific purposes. It sheds direct light on the glacial history of the Antarctic continent; in a broader sense it may reveal much of relevance to past and present world climatology. In a very different area, measurement of the flexure of the earth's crust under its enormous load of ice should yield data on crustal strength.

There are, in addition, practical as well as scientific considerations in studying the thickness of the Antarctic ice cap, as well as the Greenland, Ellesmere Island, Baffin Island, and other ice caps. If substantial portions of the Antarctic ice cap should melt, the volume of water released would profoundly influence sea level; some coastal cities might be completely submerged or develop into counterparts of Venice, with canals marking former streets. In fact, surveys indicate that certain former ice cap centers, such as Canada and Scandinavia, are rapidly rising, and many seaport towns that flourished when Rome was a world power are now marked only by their submerged ruins.(Carbon-14 dating shows that it has been only about 10,000 years since the retreat of the Wisconsin ice sheet—the last great advance of ice during the "Ice Age"—from the United States into Canada.)

Techniques of Measurement

To investigate the Antarctic ice cap, a multiple attack has been mounted utilizing the techniques of glaciology, seismology, gravity, magnetism, and geology, including photo-geology and submarine geology. In exposed-rock areas along the coasts it is possible to carry out geologic studies of the morainal material left at former positions of the ice front and to deduce the number of past advances and retreats of the ice. Similar information can be obtained from submarine cores taken from the adjacent sea floor.

From visual observation, and in particular from the study of air photos, considerable information can be obtained as to the former height of ice in valleys that may now be either ice-free or only partially ice-filled. The study of variations of ice density with depth, as observed from cores, in pits, and and from isotope dating of the ice at different depths, gives information concerning variations in the rate of ice accumulation in the recent past. While the actual thickness of ice can be obtained by drilling, this technique is both costly and slow. Only one deep boring, to study the nature of the ice rather than its depth, was included in the Antarctic program.

Seismic: The primary technique used for determining the ice thickness is that of seismology; it is based on the time it takes a sound wave to penetrate the ice and be reflected back to the ice surface from the underlying rock or water surface. This method, so long as the wave velocity in the ice is relatively constant, is as reliable for determining depth as direct drilling. Moreover, it costs only a fraction of the drilling cost, and a seismic measurement can be carried out in only a few hours compared to days, weeks, or months using a drill.

Although the time needed for a seismic measurement is small compared to drilling, it is lengthy compared to the time required for gravity or magnetic measurements, which can also be used for estimating ice thickness. These measurements can be completed in less than ten minutes. However, in contrast to seismic measurements, gravity and magnetic measurements are not significant by themselves. It is necessary first to compute a theoretical value of what the measurement should be in terms of the location and elevation of the particular observation site. The difference between this theoretical value and the observed value is used in estimating the ice thickness. Such differences are referred to as gravity and magnetic *anomalies*. As these anomalies are caused by horizontal variations in the factors measured, they form areal patterns of "highs" and "lows", which look very much like topographic contour maps.

Gravity: For effective use of gravity data, the latitude and elevation of the observation site must be known, as well as something about the density of the underlying crustal material. The force of gravity increases poleward owing to the shortening of the earth's radius as the poles are approached and to the reduced centrifugal force caused by the earth's rotation. In addition, there is a theoretical decrease of gravity with elevation, although it tends to be offset by the corresponding increase in mass of the material above sea level. In general, gravity values are related directly to the subsurface mass distribution, highs indicating excess mass and lows deficiency in mass.

Magnetic: In deriving magnetic anomalies, changes in the strength and inclination of the earth's magnetic field with both lati-

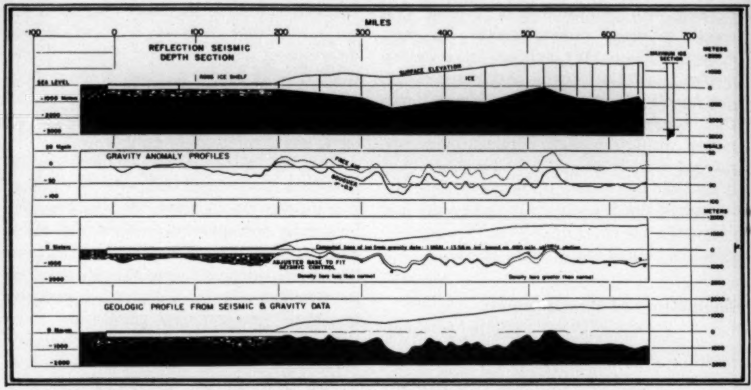

Fig. 4. *Seismic, Gravity, and Resulting Geologic Profile for Traverse Route from IGY Little America Station to IGY Byrd Station.*

tude and longitude must be considered as well as diurnal and secular, or long period, changes. To obtain magnetic anomaly values, corrections for these variations are applied directly to observed values. However, the derivation of magnetic anomalies is complicated by the fact that the pattern of highs and lows is influenced by the proximity of minor poles of magnetism induced on the boundaries of the disturbing rock mass by its geometry and its orientation in the earth's field.

Combined Techniques: By constructing profiles based on the anomaly patterns obtained by both gravity and magnetic techniques, it is possible to use the gradients on the flanks of individual highs and lows to calculate a minimum depth of origin of the anomalies. In the case of crystalline rocks underlying an ice sheet, this depth can be regarded as equivalent to the depth of the ice. Estimates of ice depth using gravity or magnetic techniques alone are far from exact, however, and errors of 20% or more are possible.

High magnetic anomalies are usually associated with gravity highs related to variations in the underlying crystalline rock, but magnetic effects resulting from variations in underlying rock configurations are small. Hence, it is possible to choose points for which the relationship between gravity-anomaly values and seismic depth measurements is significant. In this way, the gravity program can become an important adjunct to the seismic program for determining the the thickness of an ice sheet.

The method actually employed for determining the depth sections shown in the lower part of Figure 4 was to equate the seismically-determined depth below sea level at the 400-mile station to a type of gravity anomaly (Bouguer) value. This established the relation 1 mgal = 13.56m (or 44.32 ft) of ice. The Bouguer anomaly values were thus first interpreted as shown by the dashed line and then empirically adjusted on a sliding scale to account for apparent hori zontal variations in ice density, possible inclusion of morainal material, or regional variations in the kind of underlying rock. This gave the best overall fit to all of the seismic depth data. The final depth profile arrived at in this way is shown at the bottom of Figure 4. Although none of the depth

values shown in the top profile, based on seismic data alone, have been significantly changed, the overall character of the profile has been materially modified by the inclusion of the gravity measurements.

The procedure used on the IGY Antarctic oversnow traverses, was, therefore, to take seismic depth measurements at roughly 30- to 50-mile intervals and gravity and magnetic observations, which require only a few minutes, at intervals of two to five miles. This combined program of seismic, gravity, and magnetic measurements supplies geological and geodetic data as well as glaciological data.

Results

While it is too early to give comprehensive results for the program to determine ice thickness in the Antarctic, a sufficient number of seismic measurements have been made by the various international teams and on the 1957–58 oversnow traverses to show that the average thickness is 8000 ft or more. They also indicate that the underlying bedrock surface is quite irregular and that the bedrock material is probably a complex of igneous rocks. Little sedimentary rock is indicated in areas studied to date.

Marie Byrd Land and Ellsworth Highland: In Figure 5, geologic columns through the ice from the surface to bedrock, as determined seismically by various groups, are plotted at their approximate positions. Study of these columns suggests that the Palmer Peninsula may extend beneath the ice as an island, separated by a strait from Antarctica proper. The region of extreme depth to bedrock in Marie Byrd Land may mark the position of a former sea strait that became completely ice-filled as the ice cap grew.

On the first and second legs of the US-IGY Byrd Station traverse during the summer of 1957–58, which extended the earlier Little America-Byrd Station profile (Fig. 4) to the Sentinel Mountains, less than 350 mi from the base of the Palmer Peninsula, ice thicknesses ranged from about 2000 ft to 11,500 ft and, except for a few peaks, the bedrock floor was everywhere below sea level. Near the middle of the second leg, the ice rested on a bedrock floor about 6500 ft below sea level. The major portion of the area included in this profile appears to be far enough below sea level to be under water even if the ice cover were removed and isostatic balance reestablished by uplift of the ice-freed surface. On the third leg, the bedrock floor was found to be rough and mostly above sea level, with nunataks (isolated peaks breaking through the ice) appearing in several places. Near the end of the third leg, an ice thickness of over 14,000 ft—the greatest ever recorded—was measured.

Weddell Sea to South Pole: Seismic soundings taken on the Commonwealth Trans-Antarctic Expedition during the 1957–58 Antarctic summer, showed that the ice thickness increases steadily southward from Shackleton Station to the South Pole. Over much of this part of the route the ice was about 6000 ft thick. At approximately 88°30′S, however, less than 100 mi from the Pole, the bedrock base appeared to rise to within 2000 ft of the ice surface. Earlier seismic measurements at the Pole had given an ice thickness of about 8300 ft overlying a rock surface about 900 ft above sea level.

Members of the 1957–58 US-IGY Ellsworth Station traverse in Edith Ronne Land detected a deep trough extending southward from the vicinity of the Argentinian Belgrano IGY Station, about 35 mi southeast of Ellsworth Station along the edge of the Filchner Ice Shelf. The bottom of the trough has an average depth of about 3500 ft below sea level. Farther inland, the trough swings southwestward, continuing beyond the southerly limit of the traverse, which reached within about 550 mi of the South Pole. Further seismic traverse work will be needed to ascertain whether this depression extends all the way to the Ross Sea. (An early theory based on the geography and geology of Antarctica and the nearby continents of Australia and South America postulated the existence of such a trough.)

Ross Ice Shelf: Measurements made both on the 1957–58 traverse from US-IGY Little America Station and by personnel remaining at the station indicate a more or less constant thickness for most of the shelf of about 1000 ft. Near the edge, however, thicknesses range from about 790 to 1050 ft, and at the Beardmore Glacier, along the poleward margin of the shelf, the ice is 1380 ft thick. The surface of the shelf is 165 ft higher at the Liv Glacier than at the Beardmore. Since the shelf is believed to be afloat in the Liv Glacier region, this constitutes a considerable increase in ice thickness. The only evidence of grounding of the shelf was on and around Roosevelt Island and at 83°30′S, 163°–169°W.

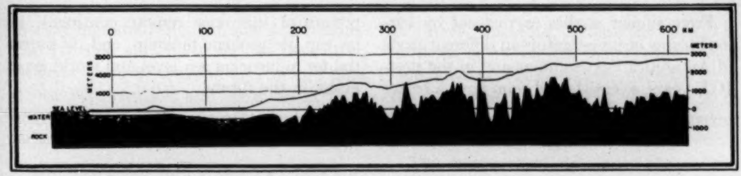

Fig. 6. *Seismic Profile Along Route of Norwegian-British-Swedish Traverse.*

Queen Maud Land: As shown in Figure 6, which is a seismic profile along the route of the Norwegian-British-Swedish expedition in 1948-52, the sub-ice surface is below sea level for at least 125 mi inland, and for a distance up to about 280 mi, there are still some areas with bedrock surfaces below sea level. The maximum ice thickness approaches 10,000 ft in the last 50 mi of the traverse. The configuration of the rock surface beneath the ice is quite irregular.

East Antarctica: During the past Antarctic summer, a party from the Australian Mawson IGY Station, at 67°36′S, 62°53′E, conducted a continuous seismic traverse for more than 400 mi south from the station. About 200 mi inland, over a point where the sub-ice surface rose to a height of 3000 ft above sea level, the ice was about 5000 ft thick. Normal ice thicknesses in this region and to the south were greater. In most places along the traverse route, the bedrock surface was above sea level.

At the USSR Vostok IGY Station, near the south geomagnetic pole almost 1000 mi into the interior of the continent, an ice thickness of 8700 ft was reported. The bedrock surface beneath the station is 2300 ft above sea level.

At station C (77°22′S, 139°48′E) of the US-IGY airborne traverse conducted in Victoria Land during the 1957–58 summer season, a possible ice thickness of 12,500 ft was measured. Distinct ice-bottom reflections were not obtained, however; it is surmised that the bottom topography in this region is too rough to serve as an efficient seismic reflector. Figure 5 shows an ice thickness of more than 9000 ft at the French Charcot Station, a few hundred miles north of station C. The bedrock surface beneath the Charcot Station is nearly 3000 ft below sea level.

Crustal Flexure

Analysis of the anomaly profiles in Figure 4 suggests crustal warping inland, with sufficient displacement of denser subcrustal material to establish isostatic equilibrium for the superimposed load of ice. It also indicates that there is no appreciable crustal flexure within the border area of the ice plateau.

The fact that the rock surface at the base of the ice is either close to sea level or well below it throughout much of Antarctica suggests considerable flexure of the continental crustal material. It is hoped that during the post-IGY period it will be possible to obtain extended gravity and seismic measurements in the offshore area so that the degree of crustal displacement caused by the ice load on shore can be directly evaluated.

Reduction of New Data

At the Antarctic Gravity and Seismological Data Reduction Center at the University of Wisconsin, profiles are now being prepared for the various traverses carried out during the 1957–58 summer season in the US-IGY Antarctic Program. The center is manned by personnel who took part in these traverse operations. Now working there are E. C. Thiel and J. C. Behrendt, from IGY Ellsworth Station, E. S. Robinson and H. F. Bennett, from IGY Little America Station, and N. A. Ostenso, from IGY Byrd Station.

From similar studies carried out by various teams of investigators in different parts of Antarctica next summer and in the post-IGY years, scientists will soon have a better picture of this once remote continent, its ice cap, its geologic makeup, and its potential for influencing sea level and world geography in the future.

Rocket Results at Fort Churchill

By July 1, 1958, a total of 116 rockets had been fired in the US-IGY Rocket Program. This number includes rockets fired in programs conducted at Fort Churchill (21 Aerobees, 20 Nike-Cajuns); White Sands (two Nike-Cajuns, one Aerobee, one Nike-Asp); Alamogordo, New Mexico (two Aerobees); Point Mugu, San Nicolas Island, California (14 Nike-Deacons, one Nike-Asp); a shipborne operation in the Arctic (18 Rockoons); and a shipborne operation in Pacific and Antarctic waters which was concluded in mid-November 1957 (36 Rockoons). (See *IGY Bulletins 7*, *5*, and *11* for accounts of the latter 3 operations.)

The major effort of the US-IGY rocket program is centered at the rocket launching facilities especially constructed for the IGY in cooperation with the Canadian Government and the Canadian IGY Committee at Fort Churchill, Manitoba, Canada. Thirty-three of the 41 launchings here have resulted in good rocket performance and satisfactory data. In addition, 6 of 7 rockets fired from the same facility prior to the IGY produced satisfactory experimental data. During a single 48-hour period in January 1958, in the midst of the Arctic winter, 5 rockets were successfully launched.

Experimental Results

Table 2 lists the rockets fired from Fort Churchill, the instrumentation carried, the performance of the rocket, and the success of the experiment. The major scientific results for each experiment are summarized below.

Participating research organizations include the Air Force Cambridge Research Center, University of Michigan, Naval Research Laboratory, Signal Engineering Laboratories, State University of Iowa, and the Army Ballistic Research Laboratories.

Ion Composition of the Arctic Ionosphere: Three Aerobee-Hi rockets instrumented with radio-frequency mass spectrometers were launched to peak altitudes of from 200–250 km. Positive and negative ions were detected on all three flights. It was found that ionized nitrogen oxide was a very important constituent of the ionosphere below 200 km and that during the daytime ionized molecular oxygen is present below 100 km and ionized atomic oxygen is present above 150 km. This new information on the electrical composition of the lower ionosphere is of great importance to theoretical studies of the interaction of solar radiation and atmospheric molecular constituents.

Structure of the Arctic Upper Atmosphere: Results from two Aerobee-Hi rockets launched during 1956–57 have been compared with structural information derived from rockets launched during 1953–54 from high altitude skyhook balloons. Tentative results indicate that at 200 km the summer daytime atmosphere density at 59°N is 2.5 times the winter daytime value; and 20 times the winter nighttime value. The summer daytime value is 6.5 times the corresponding value at White Sands, New Mexico.

At lower altitudes, between 30–45 km,

density measurements indicate that seasonal and latitude variations are less than 10%, while summer pressure measurements show Arctic temperatures and pressures at these altitudes to be significantly higher than values determined at lower latitudes.

Diffusive Separation of Gases in the Upper Atmosphere: Diffusive separation of gases under gravity in the ionosphere plays an important role in the modification of the composition of the upper atmosphere. An experiment carried out during the Arctic winter night measured the composition of the upper atmosphere between 105–240 km by means of a radio-frequency mass spectrometer. Ninety-six spectra were obtained on the ascent of the rocket and seven spectra on the descent of the rocket. Analysis of these spectra shows diffusive separation of argon and nitrogen in the region 112–150 km. Data obtained on the general composition of the upper atmosphere over the regions covered in flight also show the presence of atomic oxygen.

Meteorological Soundings: Some 30 upper atmosphere rocket soundings measured temperature, pressure, density and winds. Experiments have included the freely-falling sphere for measuring densities, the rocket-grenade experiment for the measurement of temperatures and winds, and several aerodynamic techniques for measuring pressures and densities in the supersonic flow.

Many of these rockets attained altitudes greater than 200 km, and thus the first density measurements made at high latitudes were recorded. Launchings were made during both summer and winter, day and night. The resulting data indicate that the density of the high atmosphere is under strong solar control. There appear to be a latitude effect, a seasonal effect, and a strong diurnal effect; none of these effects appear at lower altitudes at Fort Churchill or at lower latitudes.

A firing at Fort Churchill measured the first atmospheric temperature maximum at an altitude of about 60 km. Normally this maximum is found below 50 km at lower latitudes, indicating that, at northern latitudes, the temperature rise is more gradual. (Temperatures decrease up to the stratosphere, rise during the next 20 to 30 km, decrease through the next 30 km, and then rise again.)

The temperature data have shown that the winter measurement is characterized by low temperatures below 50 km. The summer results, by contrast, show extremely low temperatures at 30 km.

Winds measured at Fort Churchill have the characteristic summer-winter difference which has been observed in lower latitude measurements. The winds are weak and from the east in the summer, very strong and from the west in the winter.

Electron Density Measurements: Four Aerobee-Hi rockets have been launched to study the ionosphere above Fort Churchill. The resultant data show the ionosphere to be a single layer, strong during the day and weak at night. Two of the rockets made important discoveries. These launchings took place during "polar blackouts," periods of disrupted communications at high latitudes. The rockets have shown that the "blackout" is due to a very dense and low "D" region of the ionosphere. It has been determined that this dense region exists at a significantly lower altitude, and with a much greater density, than is found at lower latitudes. These data will be especially useful for effecting improved radio communications.

Horizon Studies—Water Vapor Structure: On March 24, 1958, the first of a planned series of five Nike-Cajun rockets was fired to obtain photographs of the horizon at a high latitude geographical location. These photographs, which show the haze surrounding the earth as a band at the horizon, reveal water vapor structure as bright lines in the haze horizon band.

Tentative results from this flight show a single tropopause structure at Fort Churchill with little evidence of fine structure. In addition, it is evident that the brightness profile

across the haze horizon increases in contrast ratio much more rapidly as a function of altitude than brightness profiles witnessed at lower latitudes.

A special parachute recovery system was developed for these flights. This was the first firing of a recovery system in this vehicle in an Arctic region. The 85-pound nose section was recovered undamaged from an altitude of 74 miles.

Field Operations at Fort Churchill

A significant reason for the success of the Fort Churchill IGY rocket sounding program has been the unique construction and operation of the range facilities under Arctic conditions. Since many of the IGY rocket research organizations are laboratories within the Department of Defense, an Interservice Support Coordinating Group was established to coordinate logistic and range facilities provided by the three services. The group consists of representatives of the Army Signal Corps, the Air Force and the Navy, all under the supervision of a representative of Army Ordnance, which assumed responsibility for the establishment and operation of the range.

The launching complex itself consists of an Aerobee tower, movable in any direction to compensate for winds, a building to house the Nike-Cajun (or DAN) launcher, preparation buildings, telemetering trailers, a blockhouse, a generator building, a helium building, and connecting tunnels. Also included and installed were two radars, range safety plotting boards and a command transmitter, a frequency monitoring station, a timing system, meteorological and wind ballistic balloon launching facilities and sites, and a complete range communications system.

Numerous instrumentation sites are installed at various points throughout the military reservation at Fort Churchill. Included are a four-station DOVAP tracking system and ballistic cameras, two telemetering trailers, two ionosphere stations, and a network of sound-ranging geophones. (See Fig. 7)

With few exceptions, the rockets fired at Fort Churchill have been equipped with radio doppler (DOVAP) tracking beacons. These beacons serve as telemeter transmitters in addition to their primary function in the tracking system. Excellent trajectory data have been obtained on all rockets either to peak altitude or to break-up on reentry. This tracking system is in use at most of the major firing ranges in the United States and in other countries. The operational record at Fort Churchill indicates that the precision of the data is such that errors

in altitude of less than 100 feet at rocket peak and in velocities of less than one foot per second have been commonplace. Such accuracies were required in many of the experiments.

An extremely important feature of the Fort Churchill IGY rocket program has been the very close cooperation of Canadian personnel. The Canadian IGY Committee and government agencies have provided most valuable assistance in the establishment and operation of this rocket range.

Life Sciences Experiments Using Earth Satellites

The possible uses of earth satellites for experiments in the life sciences were discussed by some 350 engineers and life scientists, representing both public and private institutions, at a symposium held in Washington, D. C., May 14–17, 1958. The symposium was planned and arranged by a 14-member steering committee appointed by Detlev W. Bronk, President of the National Academy of Sciences. The American Institute of Biological Sciences and the National Science Foundation joined the Academy in sponsorship of the meeting. Richard W. Porter, Chairman of the US-IGY Technical Panel for the Earth Satellite Program, served as symposium chairman.

The meeting had three basic objectives: (a) To stimulate thinking that will lead to a sound research program using earth satellites to achieve broad objectives in the life sciences, with an ultimate goal of manned space flight; (b) to exchange information concerning the technical feasibility and scientific importance of various experiments on living organisms in the satellite environment; and (c) to discuss methods and techniques for conducting such experiments, including associated laboratory work.

Some discussion of current proposals for projects in the rocket, satellite, and space areas was arranged for life scientists participating in the symposium. There was additional discussion of engineering considerations in satellite research and of facilities that may become available to life scientists in the future.

Two sessions of the meeting were devoted to discussions of experiments in basic biology in the satellite environment. At another session, biophysical instrumentation required for research in the satellite environment was discussed. Subsequent sessions covered animal physiology in satellites, behavioral research involving both animals and man, and human physiology in space vehicles. The final session was devoted to discussion of funding of biological research using satellites. Opportunity was provided during the symposium for brief papers.

It is planned to make the proceedings of the symposium available to the public and the scientific community by publication at an early date. It is hoped that this publication will form the basis for a future US program of biological research using artificial satellites as a tool.

IGY Bibliography

Beginning with this issue, each Bulletin *will carry as broad a selection of bibliographic entries relating to IGY programs and findings as space permits. The references are selected largely from an IGY bibliography under preparation in the Science Division of the Library of Congress. This month's list includes a section covering the status as of May 1, 1958, of the* Annals of the International Geophysical Year.

Status of IGY Annals

Eight volumes of the *Annals of the International Geophysical Year*, which constitute a central record of IGY activity, formal proceedings, and technical manuals used in the IGY program, have been scheduled by CSAGI (Special Committee for IGY).

Vol. I, History of IGY (in preparation).

Vol. II, Reports of IGY Conferences (in preparation).

Vol. III, IGY Instruction Manual—The Ionosphere, 381 pp., 1957.
  Part I, "Ionospheric Vertical Soundings," pp. 1-167.
  Part II, "The Measurement of Ionospheric Absorption," pp. 173-226.
  Part III, "The Measurement of Ionospheric Drifts," pp. 231-287.
  Part IV, "Miscellaneous Radio Measurement," pp. 293-381.

Vol. IV, IGY Instruction Manual, 392 pp., 1957.
  Part I, "Techniques for Radioactivity Measurements," pp. 7-17.
  Part II, "Aurora and Airglow," pp. 23-138.
  Part III, "Longitudes and Latitudes," pp. 143-201.
  Part IV, "Geomagnetism—Part I," pp. 207-245.
  Part V, "Geomagnetism—Part II," pp. 251-329.
  Part VI, "Seismology," pp. 335-344.
  Part VII, "Cosmic Radiation," pp. 349-393.

Vol. V, IGY Instruction Manual, 466 pp., 1958
  Part I, "Ozone," pp. 5-114.
  Part II, "Auroral Photography by All-Sky Camera," pp. 121-151.
  Part II, "Antarctic Radio Communication Manual," pp. 157-244.
  Part IV, "Solar Activity," pp. 249-301.
  Part V, "Radioactive Fall-Out Data and Their Interpretation," pp. 307-362.
  Part VI, "Radiation Instruments and Measurements," pp. 367-466.

Vol. VI, Instruction Manual for Rockets and Satellites (in press).

Vol. VII, List of IGY Stations (in press).

Vol. VIII, National Programs and Guide to World Data Centers (in press).

The *Annals* are published by the Pergamon Press, Ltd., 122 East 55th Street, New York 22, N. Y., and 4 & 5 Fitzroy Square, London, W.1.

IGY Rocket and Satellite Report Series

Data derived from results of experiments and observations conducted in connection with the IGY Rocket and Satellite Program are being issued in two series of reports published by the IGY World Data Center A subcenter for Rockets and Satellites. The two series are:

(a) IGY Satellite Report Series
(b) IGY Rocket Report Series

The subcenter has been established at the National Academy of Sciences by IGY World Data Center A, located in the United States (Data Center B is in the USSR and Data Center C is located in Western Europe and the Far East.)

Each report in the two series is priced at $1.00, postage prepaid. Orders should be addressed to the Publications Office, National Academy of Sciences, Washington 25, D. C.

Remittances *must* accompany orders of one dollar or less; UNESCO book coupons are accepted. Checks and money orders should be made payable to the National Academy of Sciences.

Standing orders can be placed for all titles published in the Rocket and Satellite Series. Publications on standing order are mailed as issued, postage prepaid, and are billed for periodically at a 15% discount from list price.

Special discounts are given to libraries and for quantity orders. A 10% discount is given to public libraries and to college and university libraries on orders of more than one dollar. Quantity discount rates are as follows: 5–24 copies of a single title on one order, 15% discount; 25 or more copies of a single title on one order, 20% discount; special consideration will be given to larger orders.

To date, the following reports in the Satellite Series have been published:

No. 1—Processed Observational Data for USSR Satellites 1957 Alpha and 1957 Beta
No. 2—Status Reports on Optical Observations of Satellites 1958 Alpha and 1958 Beta
No. 3—Some Preliminary Reports of Experiments in Satellites 1958 Alpha and 1958 Gamma
No. 4—Observational Information on Artificial Earth Satellites Based on Orbital Observations
No. 5—Radio Observations of Soviet Satellites 1957α2 and 1957β1 (July 1958)

NATIONAL ACADEMY OF SCIENCES

Number 14 • August 1958

IGY BULLETIN

A monthly survey by the U. S. National Committee for the International Geophysical Year. Established by and part of the National Academy of Sciences, the Committee is responsible for the U. S. International Geophysical Year program in which several hundred American scientists are participating and many public and private institutions are cooperating.

Quaternary Glaciation: McMurdo Sound Region

This report is based on material furnished by Troy L. Péwé, Glacial Geologist, USNC-IGY, College, Alaska.

A common objective of many IGY studies in the Antarctic is to learn something of the history of the Antarctic ice cap. Meteorologists are gathering data on the whole range of ice-air-sun relationships. Glaciologists are studying the history of the continent in samples of snow and ice obtained from pits and by deep core drilling. Glacial geologists are seeking to fit the rock material deposited by glaciers into the geologists' calendar of the last few thousands of years.

One of the most obvious methods of learning something about the history of the ice cap is to study the evidences of past fluctuations of the margin of this continental glacier. Today, the ice cap spills into the sea or terminates at the sea around most of the continent. The record of ice-front fluctuations, then, lies mostly under water and at the present time is relatively inaccessible. In some areas, however, considerable ice-free land is present and the record of fluctuations of the fronts of both small and large glaciers is preserved.

One of the best localities to study the record of advances of both the outlet glaciers from the ice cap and the small alpine, or mountain, glaciers not connected with the ice cap is in the ice-free area surrounding McMurdo Sound. McMurdo Sound is at the southwest corner of the Ross Sea at 165°E, 77°S, in the shadow of the Royal Society Range (see Fig. 1).

Troy L. Péwé, glacial geologist, and Norman R. Rivard, assistant glacial geologist, spent most of the period December 1, 1957–February 10, 1958, in this ice-free area. Support in transporting men and supplies to the field by helicopter was provided by the US Naval Air Facility at McMurdo Sound. Aerial survey flights were made in US Navy aircraft. Glacial deposits were examined on Ross Island, Black Island, Brown Island, Mt. Discovery, and in the dry, ice-free valleys along the west side of McMurdo Sound—from Mt. Dromedary on the south to Gneiss Point on the north.

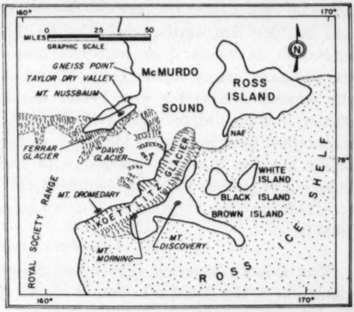

Fig. 1. *McMurdo Sound Region, Antarctica*

Glacial History

Evidence of at least three major Quaternary glaciations, each less extensive than the former, was found in the McMurdo Sound region. (A glaciation denotes a glacial advance and retreat represented by deposits and land forms distinguishable from those of different ages. The Quaternary period is the last million years of geologic time. It includes the Pleistocene and Recent epochs.)

Oldest Glaciation: The earliest glacial advance recognized in the region is indicated by patches of weathered rock material deposited by the glacier high on ridges and on elevated flat areas, such as those on both sides of the lower end of Davis Valley and near Mt. Nussbaum in Taylor Dry Valley. These deposits are 2000 ft above the valley floor. Many boulders have been abraded to the level of the ground surface by fine rock particles borne by the ever-present, strong winds. Ice of this glaciation filled all the valleys in the area and must have choked McMurdo Sound, banking at least 2000 ft up onto the surrounding terrain.

Intermediate Glaciation: Deposits of a succeeding glaciation are distributed widely around the Sound. Well-preserved but considerably wasted moraines (glacier-deposited rock material) of both outlet and alpine glaciers mark the extent of this glaciation. No sharp ridges exist and the moraines do not have cores of ice. Stones shaped by wind abrasion (ventifacts) are very well developed and boulders are wind-eroded. During this glaciation, in which there were two major ice advances, many alpine glaciers reached the expanded Koettlitz and Ferrar outlet glaciers; these alpine glaciers probably maintained their individual identities. Other alpine glaciers, however, merged with the huge outlet glaciers to fill the southern part of McMurdo Sound to an elevation of about 1000 ft.

Most Recent Glaciation: The latest major glaciation in the McMurdo Sound region is represented by the well-preserved, ice-cored moraines of the Koettlitz glacier. These are rich in volcanic materials. It is also represented by fairly well-preserved, granite-rich moraines of the alpine glaciers. Moraines of the large glaciers are characterized by many lakes and by fresh, or relatively unwasted, knob and kettle topography. The drift of small alpine glaciers is fresh but mainly represented by a thin boulder-filled clay. Ventifacts are well developed on moraines not cored with ice.

Lakes formed by blockage of valleys by glacial ice or moraines, but now drained, also existed during this latest major glaciation. The number and position of deltas in these former lakes suggest two, or possibly three, periods when the glaciers stood still or made only minor advances during this glaciation. Most alpine glaciers did not reach the sea or merge with the outlet glaciers; however, Koettlitz and Ferrar Glaciers pushed into McMurdo Sound.

Adjacent to many of the alpine glaciers are small, sharp-crested, ice-cored lateral moraines 50 to 100 ft high. These moraines are near the lower ends of the glaciers and in some places are compound. The moraines are extremely fresh and may represent minute ice advances during the last few centuries.

Regimen of Antarctic Glaciers

Comparison of the present positions of the fronts of many glaciers with their positions as shown in photographs taken 46 years ago by Griffith Taylor, a member of Scott's last expedition, reveal that little or no change has taken place in this interval. This is in sharp contrast to the movement of glacier fronts in both northern and southern temperate latitudes and supports the assumption that Antarctic glaciers have a sluggish regimen.

Conclusions

Examination of the glacial deposits in the McMurdo Sound region reveals that both the alpine and outlet glaciers have fluctuated widely in thickness and extent in the geologic past, and at least three major Quaternary glaciations are recorded. The two groups of glaciers are now independent, but in the past they merged to fill McMurdo Sound with ice. At several times in the later part of the Quaternary Period many large lakes formed when valleys were blocked by glaciers or glacier moraines. These valleys now contain only small lakes, but high-level shorelines, deltas, lake clays, and evaporite deposits—soluble salts precipitated upon evaporation of a water body—remain to attest to the former existence and extent of these lakes. (One evaporite was identified as mirabilite, or Glauber's salt, $Na_2SO_4 \cdot 10\ H_2O$.)

Although a Quaternary chronology of glacial advances and retreats, formation and destruction of lakes, and changes in sea level is recorded in the glacial materials of the McMurdo Sound region, no direct connection has yet been made with the glacial chronology elsewhere in the world.

Meteorological Rocket Soundings in the Arctic

This report is abstracted from material furnished by W. G. Stroud, US Army Signal Research and Development Laboratory, Fort Monmouth, New Jersey.

During the IGY, rocket soundings are measuring temperature, pressure, density, and winds at high altitudes in the Arctic. By the end of the IGY these soundings should yield enough data to provide a good understanding of the dynamic processes of the upper atmosphere.

Most of the US-IGY meteorological rocket soundings in the Arctic program are made from Fort Churchill, Canada (see *Bulletin 13*).

In the planning of the experiments at Fort Churchill, a guiding principle was that only proven rocket-borne techniques would be used. All techniques for observation used have been tested at the White Sands Proving Ground and have yielded significant data. The measurements have the added value of being made with the same methods in different geographic locations. Each of the techniques used, with a summary of observations, is described below.

Table 1 lists all experiments in the Arctic program and the locations and number of launchings up to June 1958. All of the US experiments, except that using the grenade technique, depend on telemetry (radio transmission of data to ground stations) from the rocket. Interpretation of most data depends on a knowledge of the trajectory of the rocket as obtained by the DOVAP system. DOVAP (Doppler-Veloc-

Table 1. *Arctic Meteorological Rocket Soundings*

ity-And-Position) establishes the trajectory by measuring phase differences in the arrival of radio signals from the rocket at three locations (see Fig. 2). All data given here are preliminary and subject to modification.

The Freely-Falling Sphere Experiment

Technique: This method of measuring the density of the atmosphere was developed by a University of Michigan group under L. M. Jones, using first Aerobees and later Nike-Cajuns. In the present procedure, a 7-inch-diameter, 9-lb sphere is carried aloft. This is ejected from the Nike-boosted Cajun. As it falls through the atmosphere, its drag is measured by means of an internal accelerometer (see Fig. 3).

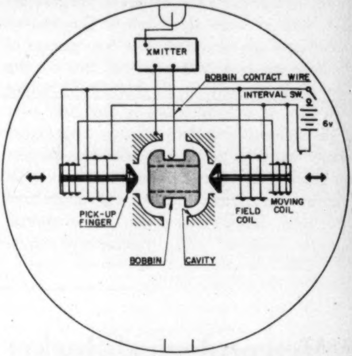

Fig. 3. *Diagram of Accelerometer in 7-inch Sphere. When the sphere is in free fall, the bobbin floats in the cavity. Drag acceleration causes the bobbin to move to the wall. The bobbin is centered and released by the pick-up fingers.*

Atmospheric density is calculated from the equation:

$$\text{drag} = \tfrac{1}{2} D v^2 C_D A,$$

where

D = density of air
v = velocity of sphere
C_D = drag coefficient
A = cross-sectional area

The drag coefficients are known from scaled wind-tunnel tests at low pressures. Velocity is obtained by timing the free-fall from peak altitude of the rocket. It is therefore possible, with the measurement of deceleration, to calculate D.

The altitudes for which the experiment is effective depend on the height from which the sphere is dropped, the ratio of the sphere's area to its mass, and the sensitivity of the accelerometer. The equipment now in use yields data for altitudes between 10 and 90 km. The accuracy is within 10% of the true value throughout this altitude range; its primary limitation is uncertainty regarding the values of the drag coefficients. Pressures and temperatures may be derived from the computed densities.

Results: Data are not yet available from the three falling-sphere experiments launched from Fort Churchill during the IGY. However, in a series of five Nike-Cajun launchings in the North Atlantic in November 1956 as part of the pre-IGY test program, density measurements were obtained up to 80 km at three latitudes. One initial conclusion is that in this region of the atmosphere the density values are less in high latitudes than in lower latitudes.

These sphere samplings, taken at latitudes of 49°, 58°, and 66°N, when compared with sphere data from Wallops Island (38°N) and White Sands (32°N) suggest that air densities at 50 km vary markedly with latitude, decreasing about 2% per degree of latitude.

The Rocket-Grenade Experiment

Technique: The rocket-grenade experiments at Fort Churchill were conducted jointly by an Army Signal Corps group under W. G. Stroud and a University of Michigan group under L. M. Jones. In this experiment, the temperatures and winds of the upper atmosphere are measured by means of explosions of charges carried aloft and ejected from Aerobees. The positions and times of the explosions in space and the times and angles of arrival of the successive sound waves at the ground are recorded by an array of microphones (see Figs. 2 and 4).

The average temperatures in the levels between grenade explosions are calculated from the relationship:

$$C = \sqrt{\frac{\delta RT}{M}} = K(T)^{1/2},$$

where

C = the velocity of sound in the layer
δ = ratio of specific heats of air
R = gas constant
T = temperature
M = average molecular weight of air
K = constant over the altitude range

The average wind speeds and directions in the air levels between grenade explosions are determined by measuring the differences between the *true* positions of the explosions (obtained by DOVAP) and their *apparent* positions as given by the angles of arrival of the sound waves at the ground. Using this method, the measured temperatures are accurate to ±5°C and the winds to ±10 m/sec in velocity and ±18° in azimuth.

Results: The ten planned Aerobee-Grenade firings of the Churchill program have been successfully completed. Five winter firings and five summer firings were made. Some were in the daytime, some at night; on January 27, 1958, firings were made at midnight and at noon to measure the day's variation of temperatures and winds up to 90 km.

The reduction of the grenade data involves the determination of the positions of each of the grenade explosions from the DOVAP records and the calculation of the angles of arrival of the sound waves. The calculation of the temperature and winds from these elements has been programmed on an IBM 650 computer, which speeds up the final steps of the reduction. However, the DOVAP reduction for positions is done

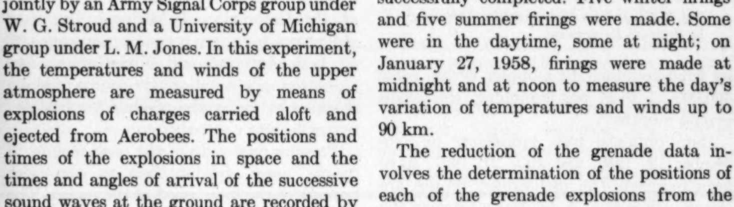

Fig. 4. *Rocket Used in Grenade Experiment*

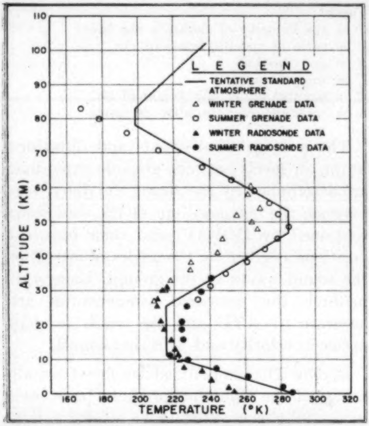

Fig. 5. *Upper Air Temperatures Measured by Grenade Experiment.*

by hand-counting the Doppler cycles, some 400,000 of them per launching; this takes several months.

Data obtained from launchings on November 12, 1956, and July 21, 1957, have been reduced. The preliminary results are shown in Figure 5. A difference between the summer and winter temperature distributions throughout the entire altitude region is shown. At 50 km, the spread is about 20°C; this is a significant amount. The winter measurement is characterized by low temperatures below 50 km and a broad, sporadic distribution from level to level. The summer sounding is, by contrast, quite smooth. It progresses to an extremely low temperature at 80 kms, 165°K (−108°C). This is the lowest temperature ever measured in the atmosphere.

The temperature data obtained from radiosondes flown at the times of the rocket soundings are also plotted in Figure 5. The soundings overlap in the 30-km altitude region and the data match quite well.

The winds measured in the grenade experiment have the characteristic summer-winter difference observed in lower latitude measurements. The winds are weak and from the east in the summer, very strong and from the west in the winter. A west wind of 150 m/sec (335 mph) was observed at a height of 58 km on November 12, 1956.

An additional finding of the Churchill launchings is the fact that above about 90 km the grenade experiment does not work. Even with four-pound explosives, sufficient energy cannot be transferred to the atmosphere to permit sound arrivals at the ground.

The Aerodynamic Experiment

Technique: In the aerodynamic experiment, a gauge mounted at the tip of the nose cone of the rocket measures stagnation, or ram, pressure. Other gauges measure pressure at the sides of the cone. N. Spencer of the University of Michigan has used alphatrons for these pressure measurements on both Aerobees and Nike-Cajuns. The alphatron uses a radioactive source of alpha particles to ionize the residual air between two collecting electrodes.

Pressure at the tip of the nose cone is, of course, much greater than on the sides because of the high speed of the rocket. The ratio of these two pressures is theoretically related to the Mach number, the ratio of the speed of the rocket to the speed of sound in the surrounding atmosphere. As the velocity of sound increases with temperature, the experiment therefore makes it possible to calculate atmospheric temperatures. The results are valid up to about 100 kms.

Results: As do all other experiments except the sphere experiment, the aerodynamic method needs detailed trajectory data before the pressure measurements can be used in evaluating other physical properties of the atmosphere.

Preliminary data from the six aerodynamic experiments indicate that between altitudes of 20 and 80 km in the Arctic, densities are 2–3 times lower than those measured previously at lower latitudes.

Gauge Experiments

Techniques: H. La Gow and his colleagues at the Naval Research Laboratory have applied earlier NRL work to measurements in the Arctic using Aerobee-Hi rockets. These measurements of pressure and density (from which temperature may be derived) are carried out as follows: Pressure gauges of various pressure ranges are scattered over the surface of the rocket, measuring stagnation and cone pressures, and pressures elsewhere on the rocket. The gauges measure pressures from 760 mm Hg to 10^{-6} mm Hg.

Roll modulation, or the change in amplitude of the gauge output with roll of the rocket, appearing on the side-cone gauges also permits the determination of the atmospheric pressure at higher altitudes (10^{-7} mm). These Aerobees are sealed throughout to prevent interior gases from leaking out. This permits an accuracy of measurement approaching the limits of sensitivity of the gauges.

This multiple-gauge approach has made possible measurements to much higher altitudes than the other techniques. Its accuracies, as given by NRL, are:

	Altitude	Error
Pressure data	25–80 km	5–15%
	110–150 km	20–50%
Density data	30–80 km	2–10%
	110–300 km	20–200%

Results: Since the accurate trajectory data required for complete analysis of the properties measured is not yet available, the reduction of data from the gauge experiments is incomplete and preliminary; however, three successful firings have been carried out at Churchill. As found in the falling sphere experiment, the densities measured are lower than those previously measured at White Sands. This seems to be true up to about 200 km. However, the measurements suggest that above this altitude summer day densities are 20 times higher than those of winter night, and winter day densities are 10 times higher than those of winter night.

Other Methods

Two other methods for measuring atmospheric density at rocket altitudes should be mentioned. Mass spectrometers for determination of gas and ion composition have obtained density data. Also, it has been observed in the grenade experiment that at the time of each explosion a period disturbance appears on the DOVAP-cycle record. This disturbance is apparently a measure of the velocity of the shock wave from the explosion. Since this is a function of air density, it becomes possible to determine the density at each grenade altitude. F. L. Bartman of the University of Michigan is at present working out this technique.

Time Variations: A specific problem in the comparison of the rocket data is that of time variations. Simultaneous measurements during the different experiments, although highly desirable, are difficult because of the limited space on the vehicles and the limited facilities for launching and tracking on range. However, at noon on January 27, 1958, an Aerobee carrying both the rocket-grenade experiment and a small sphere was launched. Twenty-nine minutes later a Nike-Cajun carrying the aerodynamic experiment was successfully launched. A comparison of the results from these three techniques will be particularly interesting and valid.

USSR Methods

The USSR is also conducting Arctic rocket-sounding programs during the IGY, using a meteorological sounding rocket to measure temperatures and pressures up to about 110 km. The USSR-IGY Committee has reported that between November 1957 and March 1958 six rockets were launched in Franz Joseph Land.

As described in Soviet literature, the

instrumentation consists of thermal and membrane manometers for measuring pressure, and an electric resistance thermometer for temperatures. An interesting feature of this technique is the use of a parachute throughout the entire downward leg of the trajectory to orient and slow the separated instrumentation section in its fall.

Previously published USSR results for the upper middle latitudes show general agreement with US-IGY results in this field.

It is still too early in the data analysis phase of IGY to draw broad conclusions. However, the prospect of obtaining meteorological data up to an altitude of 250 km at various sites throughout the world is excellent.

Ross Ice Shelf Deformation Project: 1957–58

This report is based on material furnished by James H. Zumberge, University of Michigan, Chief Glaciologist of the Ross Ice Shelf Deformation Project.

Along the margin of the Antarctic Continent are several ice shelves, thick ice formations with level surfaces, extending seaward from the land to which they are attached. One of these is the Ross Ice Shelf, the largest ice shelf in the world, extending about 500 miles in an east-west direction and 400 miles north-south.

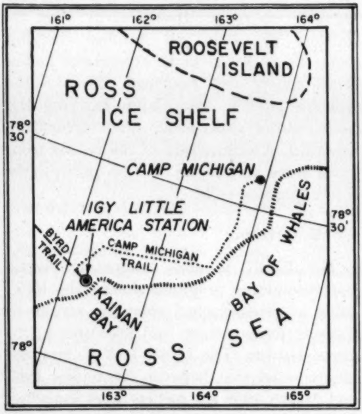

Fig. 6. *Location of Ross Ice Shelf Deformation Project, 1957–1958.*

The IGY Ice Shelf Deformation Project is concerned mainly with the measurement and mapping of deformed ice features of the Ross Ice Shelf between Roosevelt Island and the Bay of Whales. The deformation of shelf ice appears to involve some mechanism of plastic flow. If this mechanism can be determined for ice, it is possible that the results may be applicable to larger structures of the earth's crust, such as the folded Appalachians.

Camp Michigan, the base for these studies, was established on November 20, 1957, at 163°57.3′W, 78°34.0′S (see Fig. 6). The camp site is in the heart of a disturbed-ice area located by use of aircraft based at Little America Station, about 37 miles to the northeast.

During the 1957–58 Antarctic summer, Camp Michigan was supported by helicopter from IGY Little America Station. The camp itself was established by moving equipment and supplies from Little America with a 20-ton, tractor-drawn sled over a trail established November 12–15, 1957.

Scientific personnel consisted of a chief glaciologist, two assistant glaciologists, and a surveyor-photographer. A geophysical team spent approximately 10 days in the area taking seismological soundings and gravity measurements. Other temporary personnel included a Navy photographer and a Navy electronics technician.

Fig. 7. *Preliminary Map of Major Structural Features of the Ross Ice Shelf Near Camp Michigan, Antarctica.*

Triangulation and Mapping

The first phase of the study involved the establishment of a base line and triangulation network. Seventeen stations in an area of approximately 25 square miles were located and surveyed. Vertical aerial photographs were taken from an altitude of 5000 ft with a 6-inch camera. The photos overlapped sufficiently for stereographic (three-dimensional) study and radial-line plots for the establishment of a network of points on the ice surface whose positions and distances with respect to one another are accurately known.

Large-scale topographic maps were made of selected areas (see Fig. 7). This will permit details of change in the shelf-ice surface to be recognized in subsequent years.

Deformational Features

Three types of deformational features were recognized: (1) anticlines (elongated upward folds) produced in the shelf ice by horizontal compression; (2) transverse crevasses cutting across the anticlinal axes, produced by horizontal tension; and (3) structures resulting from shearing motions in the ice.

Compressional Features: The anticlines (Fig. 8) are roughly parallel; they are about 15 to 50 ft high, more than 300 ft across, and 2000 to 5000 ft long. As many as four or five nearly parallel anticlines within one square mile are not unusual in this region. Most of the anticlines are symmetrical, but a large one seen from the air was definitely asymmetrical. The similarity of these structural features of the Ross Ice Shelf to folds in sedimentary rocks of the earth's crust is apparent.

Some idea of the rate of the horizontal strain causing the anticlines to form was gained by remeasuring the baseline. The baseline was essentially at right angles to the anticlinal axes. The original length of the baseline was 5800.0 ft; 42 days later it had shortened by 7.6 ft. Another measure-

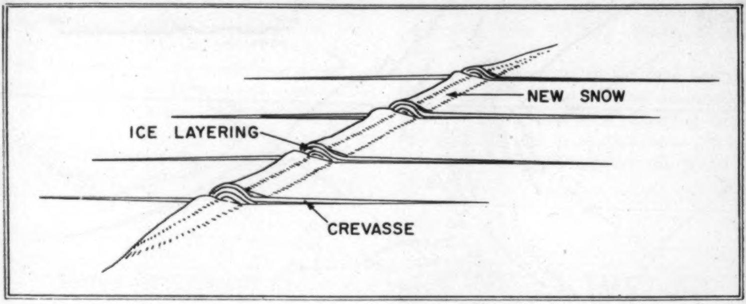

Fig. 8. *Diagram of Typical Anticline in the Camp Michigan Area. Note the layering exposed by the transverse crevasses. The individual ice layers, here greatly exaggerated, are mostly an inch or less in thickness.*

ment of the baseline one year later will provide a further check on the short-term compressional rate.

Tensional Features: Complementary to the compression-formed anticlines are evenly-spaced crevasses that cut across them at right angles to the anticlinal axes (see Fig. 8). These crevasses, produced by tension, range in width from a few inches to more than 100 ft. They are widest where they cross the anticlinal crests. Strain gauges calibrated to thousandths of an inch were installed in some of these crevasses; they showed that the rate of opening was constant, although rates differed from crevasse to crevasse. One small crevasse, 7.38 inches wide, opened 0.47 inches in 19 days. Another crevasse, 7.0 inches wide and 58 ft deep, closed at a constant rate, 0.235 inches in 25 days.

One crevasse not associated with the tensional crevasses was especially interesting because it contained a sea-ice floor 69 ft below the surface of the shelf ice. The sea-ice floor was broken by an 8- to 10-inch rift parallel to the trend of the crevasse itself, which was 41 inches wide at the bottom and about 5 ft wide at the top. The walls of the rift, 25 inches high, consisted of 9 small terraces. The width of the largest terrace was 2 inches.

The presence of the series of small terraces suggests that the ice shelf rose from time to time in this area; hence, it is assumed that the original sea-ice floor was formed when the ice shelf floated lower in the water than it did when the crevasse was examined. One possible explanation for the subsequent gain in buoyancy is that sea water was freezing onto the bottom of the ice shelf in this region. Investigations of similar crevasses that open to sea level will be made in the future to test this hypothesis.

At a depth of 25 inches below the sea-ice floor, free brine was encountered. A specific gravity test of the upper few inches of the sea-ice floor indicated a salinity of 7 ppm (parts/million) sodium chloride. Although the brine was not tested, it must have been highly concentrated since it remained unfrozen despite an atmospheric temperature at the bottom of the crevasse of about −20°C.

The walls of most of the crevasses observed did not contain secondary icing, or formation of ice subsequent to development of the crevasse, a common characteristic of crevasses in more temperate glaciers; for this reason, the walls of the ice-shelf crevasses showed excellent exposures of the ice strata.

Almost every crevasse in the study area is partially or completely covered by a snow bridge. These bridges range in thickness from a few inches over the smaller crevasses to 12 ft over a crevasse 14 ft wide and 80 ft deep. The bridges are difficult to see when light conditions are poor but they are generally easy to detect when the sun is not obscured by clouds. In some areas of the shelf, however, the snow bridges are so thoroughly incorporated into the regular surface snow pattern that no evidence of the underlying crevasses can be seen from the ground, even on sunny days. In these areas, the only effective methods of detection are aerial inspection and use of an electrical crevasse detector.

Shear Features: Shear features in the Camp Michigan area consist of crevasse systems, in echelon patterns, not associated with anticlines. Other shear features are produced late in the developmental history of the anticlines when the strain rate increases to the point where plastic deformation is no longer possible. At that time the arched form of the anticline breaks into irregular blocks. The blocks are often not recognizable from the surface but can be seen by studying aerial photographs.

Snow Stratigraphy

Snow pit studies and examination of crevasse walls were initiated in November and December 1957. A 4-meter pit near Camp Michigan in an undisturbed area revealed a stratigraphic sequence of hard and soft layers representing accumulation back to the summer of 1951. The 1951 layer formed the bottom of the pit. At a depth of 270 to 271 cm from the November 1957 surface, an ice band marks the melting which occurred during the 1952–1953 summer. This melting provided free water that percolated downward through older layers, as evidenced by vertical ice pipes (elongated bodies of clear ice formed by refrozen melt water) below the 270–271 cm ice layer.

Snow accumulation from the end of the 1956 winter to the end of the 1957 winter was 48 cm, with an average density of 0.333. This is equivalent to about 16 cm of water. Accumulation for a similar period in 1955–56 had a water equivalent of 17 cm.

Two more snow pits were dug where horizontal compression had caused the ice to fold into anticlines. One of these snow pits was placed at the bottom of the syncline, or downfold, adjacent to an anticline and the other was placed near the crest of the same structure. Both the strata studied in the snow-pits and the layering visible on the walls of the transverse crevasses cutting through the anticline showed a marked thinning toward the anticlinal crest. This occurs because newly fallen snow is swept from the exposed crest by the wind, whereas accumulation is accentuated in the adjoining synclinal trough.

Comparison of accumulation values for the years 1951–57 in the two pits showed that the synclinal trough received 40% more accumulation than the adjoining anticlinal crest; but the trough received only 5% more accumulation than was measured during the same interval in the first pit, near camp, which represented normal accumulations in the absence of unusual surface obstructions.

The importance of stratigraphic studies in the deformed areas is similar to the importance of stratigraphy in structural geology. In this particular case, it is hoped that the walls of the transverse crevasses will yield a continuous record of snow layers back to a time before the anticlines existed, that is, before the presence of anticlines exerted an influence on the local patterns of snow accumulation. With this information it should be possible to determine the rate of anticlinal growth, or more specifically, the compressional strain rate in the area.

Density Depth Profile: A density-depth profile was made from the surface to the bottom of a 36-meter-deep crevasse. Samples were taken from the walls at intervals of one meter down to a depth of 25 meters; below this, the crevasse was filled with snow from an earlier, collapsed snow bridge, or bridges. By drilling through this material to the bottom of the crevasse, the final density measurement was obtained. The density values comprising this profile, shown in Table 2, are representative for this area.

Table 2. *Density-Depth Values Near Camp Michigan*

Depth (meters)	Density (gm/cm³)
0	0.300
5	0.486
10	0.562
15	0.626
20	0.672
23	0.687
36	0.774

Thermal Studies

Thermohms (temperature sensing devices based on electrical resistance) were buried in the shelf ice at depths of 0.25, 0.50, 1.0, 2.0, 4.0, and 6.0 meters. Readings were taken once a day at 2400 GMT. A sample of the temperatures obtained is given in Table 3.

An additional temperature measurement was made at 24.5 meters below the surface in the wall of a crevasse near the camp. A probing dial thermometer inserted 3 inches into the crevasse wall in late November registered −25.0°C. (The snow bridge above the crevasse collapsed, precluding further measurement.) More temperature records will be made at greater depth during the 1958–59 season.

Meteorological Observations

Measurements were made every three hours (when possible) of temperature, barometric pressure, wind velocity and direction, cloud type, sky cover, and visibility. These records have not been completely analyzed. Generally speaking, however, the weather at Camp Michigan from November 21, 1957, to January 7, 1958, was mild. Temperatures ranged from a low of 5.0°F to a high of 34.5°F during this period. The sky was usually overcast to slightly overcast. Wind velocities ranged from 1 or 2 knots per hour to 25 knots. Winds of 15 to 20 knots were not uncommon in late November and December 1957. Prevailing winds were from the southwest but the strongest winds came from the northwest.

The strong winds and overcast skies caused difficulties in the surveying work with alidade and plane table. Overcast skies also made travel over the crevassed areas unsafe. The poor visibility prevented differentiation between snow-covered crevasses and the non-crevassed snow surface.

Future Program of Study at Camp Michigan

Camp Michigan will be reoccupied during the 1958–59 field season by a four-man team. The program of study inaugurated during the 1957–58 season will be continued and expanded. The work to be done will include the following:

1. Remeasurement of the baseline.
2. Resurvey of selected triangulation stations.
3. Aerial photography of the same area covered during the 1957–58 season.
4. Measurement of snow accumulation stakes placed in December 1957.

Table 3. *Ice Temperatures at Various Depths Near Camp Michigan*

Date	Time (GMT)	Temperature in −C°						
		Surface	.25m	.5m	1 m	2 m	4 m	6 m
24 Nov 57	2400	08.0	13.50	16.10	19.95	23.15	25.75	24.87
30 Nov 57	2400	05.0	12.35	13.85	17.70	22.40	25.60	24.87
4 Dec 57	2400	02.2	7.00	10.63	16.10	21.55	25.15	24.78
10 Dec 57	2400	06.5	9.36	12.02	15.16	20.40	24.76	24.64
14 Dec 57	2400	03.3	6.82	10.56	14.58	19.92	24.56	24.62
19 Dec 56	2400	02.6	5.58	9.26	13.62	19.18	24.16	24.52
23 Dec 57	2400	01.6	4.80	8.78	12.98	18.60	23.86	24.40
27 Dec 57	2400	02.5	4.66	7.86	12.48	18.12	23.60	24.18

5. Re-establishment of latitude and longitude by sun fixes.
6. Petrofabric studies (studies of the patterns produced by crystals) of the ice layers in deformed and undeformed areas.
7. Stratigraphic studies in snow pits and crevasse walls.
8. Further measurements of the rate at which crevasses are opening.
9. More detailed study of snow bridges and bottoms of crevasses.
10. Collection of more thermal data, with emphasis on deeper measurements.
11. Weather observations.

IGY Nuclear Radiation Investigations

The following material was furnished by Lester W. Machta and Robert List of the US Weather Bureau. Dr. Machta is chairman of the Working Group on Nuclear Radiation of the US-IGY Technical Panel on Meteorology.

At the Fourth Session of CSAGI (Special Committee for the IGY), held in Barcelona in September 1956, a recommendation by the Working Group on Nuclear Radiation to measure on a worldwide basis the radioactivity of the air, of precipitation at the earth's surface, and of solid particles deposited on the ground was endorsed.

Following endorsement of this recommendation, the Working Group met in Utrecht in January 1957. Problems related to nuclear radiation in the various fields of geophysics were discussed, and a simple collection and analysis program was formulated. The program includes establishment of a global observational network and preparation of a manual of observational standards and techniques.

The primary aim of nuclear radiation studies during the IGY is to utilize the radioactive "tracers" carried in the atmosphere and oceans to obtain a better understanding of many meteorological and oceanographic phenomena. This report describes portions of the US-IGY program of study of airborne and deposited nuclear radiation.

In addition to the information to be derived from the study of natural radioactivity, study of the artificially produced radioactive products of atomic fission and neutron-induced activities in the atmosphere is yielding much new data. With careful observation and analysis, important light may be obtained on atmospheric circulation, motions, and processes.

In this area are problems related to the identification and movement of air masses; the storage times of minute particles in the troposphere and stratosphere; exchange processes between the stratosphere and troposphere; small- and large-scale diffusion of atmospheric constituents; heat and moisture exchange between the atmosphere and the oceans; features of the large-scale circulation, including stratospheric transport; and the mechanism of precipitation scavenging—the removal of atmospheric particles by rain and snow.

US agencies participating in this program are the Atomic Energy Commission, the Geophysics Research Directorate of the Air Force Cambridge Research Center, the Naval Research Laboratory, the Public Health Service, and the Weather Bureau. In addition, cooperative agreements have been made with various agencies in other countries, especially meteorological services, to assist in sample collection and to participate otherwise in the program. With the exception of the Public Health Service program, most collections in continental United States are made at Weather Bureau stations.

Program of the Atomic Energy Commission

The New York Operations Office of the Atomic Energy Commission has two programs for collecting radioactive fallout. One consists of exposing one-square-foot sheets of gummed cellulose-acetate film on horizontal surfaces about three feet above the ground. Collections are made daily at 39 stations in the continental United States and cooperatively at 81 stations elsewhere in the world. At each station, the film is left exposed for 24 hours, then mailed back to New York. Here, the film is reduced to ash, placed in a plastic planchet and fed through an automatic counting device, where the total beta activity of the sample is determined.

The second program consists of continuously exposing to the atmosphere high-walled, stainless steel pots 0.82 square ft in area. Such pots are in use at 10 stations in continental United States and 16 elsewhere in the world. Each month, the contents of the pots, rinsed with distilled water if necessary, are bottled and shipped to New York for analysis of gross fission products, beta activity, and strontium-90 content. A gradual expansion of the station network is anticipated.

Program of the Public Health Service

The Public Health Service Radiation Surveillance Network, operating cooperatively with the Atomic Energy Commission, consists of 42 field sampling stations and a central laboratory. The central laboratory and three of the field stations are operated by the Public Health Service, the remainder of the stations are under the supervision of the appropriate state or territorial departments of health. Personnel are furnished either by the States or by cooperating local health departments.

Measurement of the concentration of fission products is made by filtering air through a four-inch-diameter dust filter at a rate of about 34 ft^3/min. Two sampling schedules are used: (1) continuous sampling for 24-hour periods, and (2) sampling on a timer-controlled schedule of one hour out of every three over a period of approximately 3½ days. The station operators estimate the activity on a filter and then send it to the laboratory in Washington, D. C., for counting. The filters are measured for beta activity with a thin-window, 7½-inch, gas-flow proportional counter. Each sample is counted at least three days after collection and again seven days later. On the basis of these two activity measurements, and assuming that the beta activity has decayed according to the Way-Wigner formula (radioactive fission products decay at a rate proportional to $t^{-1.2}$, where t = time from the formation of the products), the activity is extrapolated back to the end of collection.

Precipitation samples are collected by 20 of the network stations. When precipitation occurs, one sample is taken during each sampling period. The sample is collected in a bottle using a funnel 0.4 square meters in area. At the collection site, 0.5 liters of the collected precipitation is evaporated to dryness in a rectangular aluminum dish. The dish is then sprayed with plastic, flattened, and mailed to the central laboratory for counting. Activity is extrapolated back to the end of collection in the same manner as with the air filters.

Program of the Naval Research Laboratory

The program of the Naval Research Laboratory is carried out at a network of 20 stations extending along the 80°W meridian from Thule, Greenland, to Punta Arénas, Chile. Daily air-filter collections are made at all stations. In addition, four stations elsewhere are making weekly air-filter collections, and a complete air monitor unit is in operation at IGY Little America Station, in Antarctica. Cooperative agreements with the various participating governments and agencies are in effect.

Each station making daily collections is equipped with a positive-displacement air pump driven by a constant-speed electric motor. This apparatus pumps about 30 ft^3 of air/min through a filter paper 8 inches in diameter. Filters are changed each morning and forwarded to the Naval Research Laboratory in Washington, where they are burned to ash at a temperature of 650°C, and compressed until wafer thin. Counting is done with a thin-window, halogen-filled G.M. tube. Each sample is counted 14 days after collection. Weekly collections are made with a larger filter (17 × 13 inches) having a flow rate of 35 ft^3/min.

Monthly composites of individual samples from each station are being analyzed for the following radioisotopes: Sr^{89}, Sr^{90}, Y^{91}, Cs^{137}, Ce^{141}, Ce^{144}, and Pb^{210}.

The equipment at Little America Station automatically monitors the filter during collection and follows the rate of decay during the next 18 hours. In this way, information is made available on natural radioactivity as well as on fission-product activity.

Program of the Air Force Cambridge Research Center

Six of the stations in the 80°W network of the Naval Research Laboratory program are also participating in the Cambridge Research Center program. At these stations, all of which have appreciable precipitation, the precipitation is collected and sent to a laboratory to be analyzed for Sr^{90}, Pb^{210}, tritium, and other individual radio-isotopes. Measurements of Sr^{90} are made on all samples; only selected samples are used for the other elements. In addition, snow cores and fresh snow from Greenland and the Antarctic are analyzed.

World Warning Agency Decisions

January 1, 1958—June 30, 1958

During the first six months of the IGY, 16 periods of Alerts and 7 SWI (Special World Intervals) were declared by AGIWARN, the IGY World Warning Agency, operated by the National Bureau of Standards at Fort Belvoir, Virginia, near Washington, D. C. (See *Bulletins 5* and *7* for details in this six-month period.)

During the next six-month period 11 Alerts were declared covering a total of 46 days and 6 SWI, covering 16 days, were declared.

Following are the Alerts, SWI, geomagnetic disturbances, and major flares that occurred from January 1, 1958, to June 30, 1958. Alerts and SWI are numbered serially from Alert number 16, which ended on December 29, 1957, and from SWI number 7, which ended on November 27, 1957.

IGY World Data Centers and Data Interchange

In accordance with the recommendations of the Third Assembly of CSAGI (Special Committee for IGY) in Brussels in 1955, three World Data Centers were established to maintain collections of IGY data. It was decided that three data centers would insure against the loss or destruction of the data and would serve the geographical convenience of scientists of all nations.

Two IGY National Committees, those of the USA and the USSR, each offered to establish and maintain collections of all the data. These centers were named A and B respectively. A third center, C, is in Western Europe, Japan and Australia. For several disciplines two subcenters of World Data Center C have been established, and are designated C-1 and C-2.

World Data Center A

World Data Center A was established in eleven institutions in eight cities of the United States and Alaska. The U. S. National Committee believes that the interests of science are served best by establishing subcenters for the various disciplines in the institutions which have a history of scientific interest and competence in the appropriate geophysical field rather than by establishing one central archive. The National Academy of Sciences is responsible for the direction of World Data Center A.

The subcenters of World Data Center A are:

(a) *Airglow and Ionospheric Physics:* Central Radio Propagation Laboratory, National Bureau of Standards, Boulder, Colorado. Director: W. B. Chadwick, Chief of Regular Propagation Services Section of Radio Propagation Physics Division of the National Bureau of Standards.

(b) *Aurora (instrumental observations):* Geophysical Institute, University of Alaska, College, Alaska. Director: C. T. Elvey, Head of the Department of Geophysics and Director of the Geophysical Institute of the University of Alaska.

(c) *Aurora (visual observations):* Rockefeller Hall, Cornell University, Ithaca, New York. Director: C. W. Gartlein, Technical Advisor for Physics and Director of the Cornell Study of Aurora.

(d) *Cosmic Rays:* School of Physics, University of Minnesota, Minneapolis, Minnesota. Director: Paul J. Kellogg, Research Associate in the School of Physics, University of Minnesota.

(e) *Geomagnetism, Gravity and Seismology:* U. S. Coast and Geodetic Survey, Geophysics Division, Washington, D. C. Director: J. H. Nelson, Chief, Geomagnetism Branch, U. S. Coast and Geodetic Survey.

(f) *Glaciology:* American Geographical Society, Broadway at 156th Street, New York, New York. Director: William O. Field, Head of the Department of Exploration and Field Research, American Geographical Society.

(g) *Longitude and Latitude:* U. S. Naval Observatory, Washington, D. C. Director: William Markowitz, Director of Time Service, U. S. Naval Observatory.

(h) *Meteorology and Nuclear Radiation:* National Weather Records Center, U. S. Weather Bureau, Asheville, North Carolina. Director: Helmut E. Landsberg, Chief, Climatological Services, U. S. Weather Bureau.

(i) *Oceanography:* Department of Oceanography and Meteorology, Agricultural and Mechanical College of Texas, College Station, Texas. Director: Dale F. Leipper, Head, Department of Oceanography and Meteorology, Agricultural and Mechanical College of Texas.

(j) *Rockets and Satellites:* National Academy of Sciences, Washington, D. C.

(k) *Solar Activity:* High Altitude Observatory, Boulder, Colorado. Director: Walter Orr Roberts, Director, High Altitude Observatory of the University of Colorado.

Current Status of Data Flow

The current status of the flow of data to World Data Center A and of the interchange of data between Center A and the other World Data Centers is set forth below for each subcenter of Data Center A. The second "6-monthly" catalogue of data on hand in World Data Center A was issued on June 10, 1958. It may be noted that the flow of data most nearly approximates the CSAGI schedules in those disciplines in which there was organized international exchange of data prior to the IGY.

To date, World Data Center A has received data from 58 of the 66 nations participating in IGY including all of the larger nations. Data are also being received from stations and nations not formally part of IGY, and some data are being sent for times prior to the commencement of the IGY.

Airglow and Ionospheric Physics: The amount of data received in airglow projects is small at present because processing is laborious. A few months of data have been received from four nations. Some data have been sent to and received from each of the other World Data Centers. Since absolute calibration of IGY airglow photometers has now been completed, data for the first year of observations should reach the data center in the near future.

The flow of ionospheric data is immense. Data have been received from each of the other World Data Centers, and directly from 145 stations in 43 nations. Approximately 320,000 feet (61 miles) of ionogram film have been processed. The dispatch to other Data Centers of data received by Center A is fully current.

To date, fourteen requests for data have been received, and several scientists have already visited Boulder to work with the data on the premises.

In addition to the CSAGI 6-Monthly Catalogue, an interim catalogue of data in Center A for airglow and ionospheric physics was issued in April.

Aurora (instrumental): Data from instrumental auroral studies are flowing more slowly than anticipated. More time has been required to process and reduce all-sky camera films and transmit them to the Data Center than was estimated in the CSAGI schedule. Nevertheless, at present, film has been received from 22 of the all-sky cameras operated by U. S. projects.

Aurora (visual): In the United States there are 424 active volunteer observers from whom 16,000 positive and 50,000 negative reports of auroras have been received. The US Weather Bureau has furnished 20,000 positive and 300,000 negative reports. From these reports, over 1000 auroral maps for 15-minute intervals have been drawn at the Regional Center at Cornell.

Data for the first eight months of IGY have been dispatched to the other World Data Centers. Data have been received from Data Center C. In addition, data have been sent directly to Center A from Argentina, Canada, Cuba, Mexico, and New Zealand.

Cosmic Rays: Data are flowing regularly to Data Center A from Centers B and C. Many stations send data directly to Center A. To date, data have been received at Center A from 21 of the 38 nations participating in the IGY program in cosmic ray studies.

The flow of cosmic ray data during the past five months has been more than five times as great as during the first six months of IGY. Approximately one-third of the stations are up-to-date in their transmittal of data to the centers.

Geomagnetism, Gravity, and Seismology: Magnetic data have been sent to Center A from nations in the Western Hemisphere for forwarding to the other World Data Centers. No data have been received directly from the other World Data Centers; stations which send primarily to these centers send also to Center A, usually through a collecting agency.

Geomagnetic data have been received from 86 stations in 27 of the 49 nations participating in the geomagnetic program. Many requests have been received for geomagnetic data, including requests for the data from the entire chain of variograph stations in the Western Hemisphere.

The flow of gravimetric data has been small as yet. Data sent to World Data Center A include earth tide studies at three stations in Japan and one station in Hungary.

Bulletins containing seismic data have been sent directly to Data Center A from stations or national collection agencies of 22 of the 52 nations which are participating in the IGY program. The bulletins received to date include data from 165 stations.

Glaciology: The flow of data to the subcenter for glaciology has been limited to progress reports from 13 glaciological projects in Canada, New Zealand, and the United States. The basic data for the field work accomplished during the first Antarctic summer, which ended in March of this year, is being compiled and should be transmitted to the Data Centers within the coming four months. This Center has issued the first volume of the World Data Center A Glaciology Report Series. This volume includes preliminary reports received by the Center prior to June 23, 1958.

Longitude and Latitude: Data from the two programs in longitude and latitude are reaching the appropriate primary data centers: astrolabe data to Paris, moon position data to Washington. These data will be reduced and published by the primary data centers. The flow of moon position data began only recently because of delays in starting the observation program.

Meteorology and Nuclear Radiation: Most stations submit data directly to World Data Center C. Data from stations in the Western Hemisphere have been forwarded to Centers B and C as required.

Center A has received data from 35 nations, including microfilm for three months of data from the USSR Data Center. A similar amount of microfilm has been dispatched to the USSR Data Center.

The flow of data to Center A from the stations in the United States and North America alone amounts to 25,000 punched cards per day—for the entire world network of stations the data will require about 100,000 cards per day. These data will be reproduced on Microcards by World Data Center C.

The pattern for the flow of data on nuclear radiation was established several months after the beginning of IGY. Center A has received data on nuclear radiation from eleven nations participating in this program.

Oceanography: Sea level data from ten countries have been sent to Data Center A. Cruise reports have been received from nine nations for 39 ships. Data have been sent to and received from World Data Center B. World Data Center A issued an interim catalogue of data received prior to April 1, 1958.

Rockets and Satellites: The CSAGI Guide outlining the operation of the Data Centers for rockets and satellites was issued in April 1958. Prior to this time, very little data had been received by this Center. Because of the nature of rocket and satellite data results, the agreed-upon timetable allows twelve months after completion of an experiment before data are expected. Data have been received at Data Center A from Denmark, Germany, Japan, South Africa, United Kingdom, United States, and USSR.

In order to make the results of rocket and satellite experiments widely available to interested scientists, Data Center A initiated two series of reports: one for rockets, one for satellites. Five issues of the satellite series and one issue of the rocket series containing preliminary data have been published. Some preliminary and informal reports have been received from the USSR, descriptive of their satellite experiments and early results.

Solar Activity: Data flow very promptly in this discipline. Center A has received data from 24 of the 36 nations participating in the solar activity program. In addition to the telegraphic data, written and tabulated reports are received regularly and promptly. Monthly lists of solar flares are dispatched by the 7th of the following month.

As part of the intermediate publication of data, Center A has published Solar Activity Report Series Numbers 1-3, "Reports of Surges and Active Prominence Regions," for the months of July 1957–March 1958.

Reports

In addition to the reports issued by the individual centers, a General Report Series has been established by World Data Center A. The first volume of this series is "Description of the Antarctic Circulation Observed from April to November 1957 at the IGY Antarctic Weather Central, Little America Station." This report is the work of Vladimir Rastorguev of the USSR and Jose Alvarez of Argentina, who spent one season at Little America.

The second volume of the IGY General Report Series is a preliminary report of the "Downwind Expedition" of the Scripps Institution of Oceanography of the University of California. The third volume includes three preliminary reports on the gravity and seismic programs at the University of Wisconsin.

IGY Bibliographic Notes

This is the second of a series of bibliographic notes of IGY programs and findings. The references are selected largely from an IGY bibliography under preparation in the Science Division of the Library of Congress.

The Geochemistry of Tritium*

BRUNO J. GILETTI, FERNANDO BAZAN, AND J. LAURENCE KULP

Abstract—The tritium concentration has been determined in precipitation, ocean waters, and ground waters. Although the steady-state tritium 'cycle' has been disturbed by thermonuclear testing, enough analyses of pre-test water have been made to conclude that: (1) the North Atlantic surface water had a natural mean $T:H = 1.0 \times 10^{-18}$ which doubled in 1954 because of the Castle tests, (2) this water mixes down to the seasonal thermocline in one year, (3) the North Atlantic Central Water appears to be 25 years old off the coast of Portugal, (4) measurable tritium was found in three bottom samples in the North Atlantic suggesting a young age for some of that water, (5) the hot waters of the Tecolote Tunnel, California, were from recent (nine months) rains, (6) direct runoff of precipitation from the ground surface to streams was at least three per cent of the total precipitation in the Hudson River basin in 1954, (7) the natural rate of production of tritium is calculated from a budget on the North Atlantic to be 0.75 ± 0.4 H^3 atoms/sec cm^2 of Earth's surface.

Introduction—Tritium (H^3 or T) is constantly being produced by cosmic rays in the upper atmosphere, combining with H and O to form HTO, and then entering the water cycle. It is beta radioactive, with a half-life of 12.262 years [*Jones*, 1955] and is therefore useful for certain global tracer experiments.

The discovery of tritium in natural molecular hydrogen in the atmosphere by *von Faltings* and *Harteck* [1950] led to a search for H^3 in natural waters, subsequently achieved [*Grosse* and others, 1951]. The first extensive survey of tritium in natural waters was made by *Kaufman* and *Libby* [1954]. Subsequent studies have been made by *von Buttlar* and *Libby* [1955], *Begemann* and *Libby* [1957], *Fireman* and *Schwarzer* [1954], and *Brown* and *Grummitt* [1956].

An attempt has been made in this investigation to determine the processes and rates of mixing in the atmosphere and oceans. From this information and a consideration of the tritium cycle, the cosmic-ray production rate of tritium is derived.

Procedure—The analysis of the natural waters for tritium concentration involved electrolytic concentration followed by gas proportional counting of hydrogen gas. With present counting techniques, the limit of detection of the ratio of tritium atoms to total hydrogen atoms is $T:H = 1 \times 10^{-16}$ for hydrogen liberated from a 1.4 ml sample of water. Since many samples fall in the range of 10^{-18}, the tritium in the sample must be concentrated before counting.

Techniques developed by *Brown* and *Daggett* [1935] and *Kaufman* and *Libby* [1954] were used [*Giletti*, 1957]. First the water sample is electrolyzed, thus liberating protium preferentially to tritium. The extent of enrichment is monitored by deuterium analysis. Volume reductions by factors of 100 to 10,000 still leave about one half of the initial moles of tritium in the residual water.

The concentrated water sample is converted to H_2 gas by diffusing the water vapor over granulated CP zinc at 400°C. The reaction is quantitative producing H_2 and ZnO.

The counting procedure was developed at this laboratory. A two-liter copper gas proportional counter is filled to 0.9 atmosphere with the sample H_2 and 0.1 atmosphere of purified tank methane. The methane is used to improve counting characteristics. Backgrounds on the two counters are stable to ±0.3 cpm (the backgrounds are 9.5 and 13.8 cpm respectively). For a detailed description of the analytical procedure, see *Giletti* [1957].

Samples of water containing no tritium (such as water prepared by burning dry natural propane in a closed system with specially dried oxygen) were analyzed and found to have a blank value of $T:H = 0.3 \pm 0.1 \times 10^{-18}$. A careful search for the source of this contamination has suggested condensation of water vapor in the electrolytic cells but the problem is not entirely solved. The blanks were quite consistent, however, so that within the error stated above, the correction is reliable. The blank value is not a function of the extent of electrolytic enrichment. The volume enrichment factors vary at least threefold with no consistent variation in the blank value.

RESULTS

The results are presented in units of T:H × 10^{18}. These concentrations have had the blank value of T:H = 0.3 × 10^{-18} subtracted from them and have been corrected for the decay of tritium between the times of collection and counting. For all values of T:H > 1 × 10^{-18}, the error is a 1 σ of 10 pct. The blank correction error dominates in the lower concentrations. Tables 1–5 list the results obtained at this laboratory grouped into suitable categories. The Lamont precipitation data are listed chronologically (Table 1), the European results are listed in a north to south direction (Table 3) and the Atlantic subsurface data are listed as a function of depth (Table 5).

METEOROLOGICAL OBSERVATIONS

Analyses of rains and moisture for tritium and some correlation with meteorological data were performed by *Kaufman* and *Libby* [1954], *Fireman* and *Schwarzer* [1954], *von Buttlar* and *Libby* [1955], *Brown* and *Grummitt* [1956], and *Begemann* and *Libby* [1957]. The analysis of rains at Lamont began in the fall of 1953 (Table 1). The overall results are in good agreement with those of the University of Chicago workers. Figure 1 shows the data of both laboratories for a two year period. The logarithmic scale tends to minimize the variations. The early results yield a mean value of 8.4 × 10^{-18} and are considered the natural tritium level if cosmic-ray production only is involved.

Following the explosion of the first thermonuclear device significant to this study, in March 1954, as part of a spring test series in the Pacific, very high and highly variable results were observed until early June of that year (Fig. 1). As a result of the high temperatures at the explosion site, most of the T atoms produced would probably

burn rapidly to form HTO and become a part of the moisture content of the air. It is possible, therefore, to calculate the time of washout of the moisture into the Earth and oceans by following the 'decay' of the tritium concentration in rain. Figure 2 shows the pertinent portion of the data. The figure gives all Lamont tritium data in this period. This half-life of retention in the atmosphere was calculated by a least-squares fit to the data to be 35 days. This agrees well with data of *von Buttlar* and *Libby* [1955] and *Brown* and *Grummitt* [1956] but must be regarded as a maximum value since more than one pulse may have been involved.

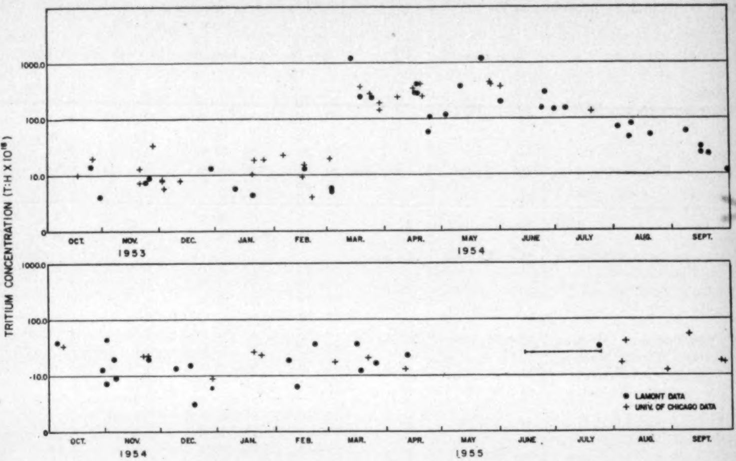

FIG. 1 – Tritium concentration in precipitation from 1953 to 1955

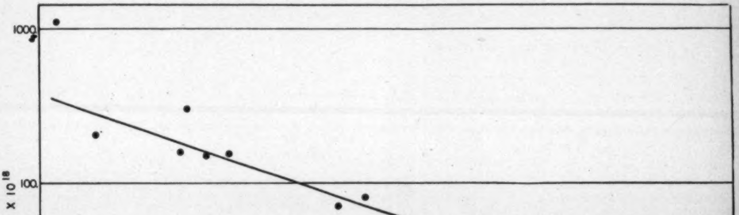

FIG. 2 – Tritium concentration of Lamont rains immediately following the Castle tests 1954; the line is a least-squares fit and gives a $t_{\frac{1}{2}}$ = 35 days

The period following the 'decay' of this atmospheric activity begins at about the beginning of October 1954. During this time a relatively constant T:H is found which is comparable to that for 1953. However, the concentration averages 18.4 (or an increment of 10 over the earlier period). With the rapid washout time this new level must reflect either a large stratospheric reservoir from the Castle and later tests or continuous introduction of tritiated water at ground level from other sources.

Atomic test effect on precipitation—During the period under observation numerous tests were made of atomic devices. It is important to establish the extent that such tests could affect the 1953 data. All subsequent calculations on natural tritium levels of activity are based on the 1953 assay.

The United States conducted two major series of tests during the period under discussion. These occurred in November 1952 and in the spring of 1953. The 1952 tests included the first thermonuclear test explosion. This might be expected to yield tritium concentrations similar to 1954. *Kaufman* and *Libby* [1954] found no such values. The maximum in their data was 66 (as compared to this laboratory's 1240 in 1954). Thus the maximum increment was 4.4 pct of that during the 1954 Castle tests. These authors also obtained the following data:

Sample date	$T:H \times 10^{18}$
Nov. 18, 1952	66 ± 1.0
Nov. 22–25, 1952	19.3 ± 1.5
Dec. 2, 1952	13.2 ± 1.2
Jan. 6, 1953	7.1 ± 0.5

This may be a 'decay' curve or it may represent random variations. At any rate, no extended period of high values such as Mar.–June 1954 occurred. The decay, if any, started immediately. Hence the total increment of tritium (as opposed to the comparison of peak values) must be considered as less than two per cent of that in 1954.

The major increment to the oceans caused by the Castle tests had occurred by the late summer of 1954 (see below) as a result of the large tropospheric fallout. The long-range fallout from the stratosphere added a maximum increment of T:H = 10 for rains at Lamont. Assuming that the increment to 1953 was 8 (that is, the total T:H of the rains) then this would not have been enough to supply the oceans with the tritium observed. However, some increment less than the full T:H = 8 is all that can be assumed. This would affect the oceans by less than two per cent. Thus the 1952 test could not have changed the Atlantic Ocean value and hence the world reservoir estimate, by more than four per cent.

A further question as to the 1953 assay of world tritium arises in connection with the more conventional atomic fission tests. Since a considerable neutron flux is produced, n, t reactions on nitrogen might produce significant tritium. The United States conducted a series of tests in Nevada during the spring of 1953. The data of *Kaufman* and *Libby* [1954] for the spring and summer of 1953 are monotonously constant at about $T:H = 6 \times 10^{-18}$ suggesting no effect from A tests.

Rains at the Brookhaven National Laboratory showed some high tritium contents in 1953 [*Fireman* and *Schwarzer*, 1954]. Two of these rains had T:H ratios of 300 and 800 respectively. There are isolated cases, however, one appearing in August well after the United States tests were over. It is suggested that those rains either reflect the recycling of local laboratory tritium waste from Brookhaven or possibly contamination of the sample. It is concluded that the fission tests are not significant tritium producers.

Geographical tritium variations—The rain study was extended to Europe in 1954. The samples were taken on a traverse from Hammerfest in northern Norway to Madrid, Spain. These data (Table 3) indicate that for comparable latitudes (New York and Spain) the tritium concentrations in surface waters and rain in the latter part of August 1954 were similar. The values decrease somewhat northward probably reflecting the path of the thermonuclear cloud.

The ten northernmost samples average 18.9 while the others to the south (nine samples) average 32.2.

The variations observed in the T:H before March 1954 were presumably of natural origin. A comparison of the T:H ratio to the amount of

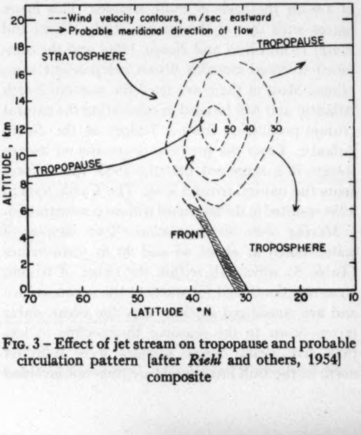

FIG. 3 – Effect of jet stream on tropopause and probable circulation pattern [after *Riehl* and others, 1954] composite

precipitation showed that while considerable variability exists in storms with less than one inch of rain, those with more rain have a T:H < 6×10^{-18}. Thus it is only in cases of extreme dilution that the T:H is significantly affected.

It is suggested that the reason for the variable tritium concentration is jet-stream activity [*Milic*, 1956; *Machta*, 1957]. It is generally accepted that a low-pressure area is often associated with a jet stream at higher altitudes [*Riehl* and others, 1954]. A composite section (Figure 3) illustrates the relationship to the upper air circulation. It was suggested by *Riehl* and others [1954] that air is transferred across the jet stream as shown by the arrows. The higher tritium concentrations in the stratosphere could then affect the T:H in rain in varying degrees.

OCEANOGRAPHY

Tritium enters the oceans from rainfall and exchange at the surface. The value of tritium as a tracer of water masses depends on the definition of the T:H ratio in the surface ocean water. The most obvious application is to the mixing rate of the surface layer. If the rates are fast enough the tritium tracer can also be used to follow the mixing of surface with deeper water.

A survey of North Atlantic surface water was begun in 1953 and is continuing (Table 4). The mean value for 1953 was 1.0×10^{-18} but by 1954 it had risen to 1.9×10^{-18}. Although *von Buttlar* and *Libby* [1955] reported a value of 0.58 for the 1953 North Atlantic surface water, a recent report by *Begemann* and *Libby* [1957] gives the average of 1.0 on the basis of more samples. This figure agrees with that of the present study [*Giletti* and *Kulp*, 1956; *Giletti* and *Bazan*, 1956] and the combined average includes fifteen independent samplings. Most of these are from the western North Atlantic and will be used in calculating the natural tritium production from a budget of the North Atlantic. From the previous discussion on meteorology, it is suggested that the 1953 value represents the natural trituim level. The Castle tests in 1954 resulted in the increased tritium concentration.

Mixing above the thermocline—Two samples of water taken at about 45 and 90 m yield values (Table 5) which fall within the range of tritium concentration found for water at the ocean surface and are considered to show that the ocean water mixes down to the seasonal thermocline in less than five years. These samples were collected north of the Gulf Stream and are thus not involved in the formation of the North Atlantic Central Water. A sample of surface water taken on July 15, 1955 (Table 5) showed the thermonuclear effect of the previous year at a depth of 46 m. It is concluded that the assumptions based on temperature and salinity data of vertical mixing of the surface layer (that is, upper 50 m) within one or two years are confirmed.

North Atlantic Central Water—Two samples of North Atlantic Central Water (NACW) were measured, September 19, 1954 and July 19, 1955, giving values of 0.22 and 0.30 respectively. If the water were flowing in a closed pipe with the surface of the ocean the origin, the age would be about 25 yr. The mean flow rate from the convergence area to the eastern Atlantic at the location of the 1954 sample (36°51′N, 14°00′W) would be ~0.4 cm per sec.

If lateral or vertical mixing were taking place, the water would be a mixture of 25 pct surface and 75 pct old deep water (at least 50 years old). Other combinations are possible as well as a combination of mixing with some direct flow. Since the NACW increases in density with depth, it is possible that lateral mixing or mass flow are occurring at different rates in any given section. Very closely spaced samples in vertical profiles at a number of selected locations would be needed to determine this mechanism. The tritium in the upper portions of the NACW, however, may indicate measurable tritium throughout the mass, although perhaps in lower concentration. If the T:H were 0.2×10^{-18} throughout the Central Water, the calculations on the production rate of tritium would have to be revised significantly (perhaps tripled). Thus it is unlikely that a T:H > 0.1 will be found for the average NACW.

North Atlantic Deep Water (*NADW*)—This water has been found by its natural radiocarbon concentration to have a mean age of 600 yr [*Broecker*, 1957] and is considered to have a T:H < 0.01. The values obtained were $-0.02 \pm .1$, $+0.02 \pm .1$, $+0.03 \pm .1$ (Table 5) all in the usual T:H $\times 10^{-18}$ units. The NADW is thus certainly less than 0.05×10^{-18}. These were samples collected at 1830 and 3660 m depth.

Bottom samples—Three samples were analyzed which come from 40 m above the ocean bottom. These had T:H values of 0.2, 0.48, and 0.40 (Table 5). These results if not caused by contamination suggest that some water which originates in high latitudes at the surface moves rapidly along the bottom to 37°N. If this is true a latitude effect might be observed in the bottom water. The density gradient above the bottom water is small so that upward mixing is possible. Thus the tritium in the bottom water would tend to become diluted with the overlying 'dead' water as it proceeded southward.

The transfer mechanism might be either by direct flow or eddy transfer. The major process would have to involve mixing with the Deep Water alone rather than an age effect since C^{14} measurements do not show markedly different values between the core of the NADW and the bottom water.

It can be concluded that tritium measurements on some of the Atlantic waters are not only possible but useful. Further study in the surface waters and Central Waters should be particularly fruitful, and the bottom water offers intriguing possibilities. A distinct change in T:H is observed between the surface waters and the NACW. This supports the conclusions from the standard T-S analysis that the two water masses do not mix extensively.

HYDROLOGY

Continental surface waters—The response of surface waters to the increased tritium in rains is rapid but varied. The New York City water supply consists of a system of reservoirs north of the city in the Manhattan Prong and the Catskill Mountains. A sample from one of the reservoirs (Monroe Pond) gave a $T:H = 7.4 \times 10^{-18}$ (Table 2) February 6, 1954. *Von Buttlar* and *Libby* [1956] list two other reservoirs at 7.2 and 8.4 so a mean $T:H = 8$ will be assumed. This coincides with the mean tritium content of pre-Castle New York rains, as might be expected from rather small lakes which may turn over in only a few years. All of these samples were collected on February 6, 1954. The first 'hot' rain occurred on March 14, 1954, and the tap water in New York City on April 10 was already up to 28 (Table 2). The Hudson River also showed a marked increase by March 30 with a $T:H = 29$.

Hudson River runoff—The Hudson River sample was taken at an opportune time to measure the amount of water which enters the stream directly. The river is supplied both by surface runoff and ground water. If precipitation enters the ground in the watershed area, it will tend to force other waters to leave the ground and enter the stream. On the other hand, some of the precipitation will enter the stream directly. These two sources combine and the waters in the stream can only be studied as an integrated whole. From the point of view of erosional effects, however, the surface flow is important.

Since the Hudson was sampled shortly after the first significant thermonuclear tests, the rainwater entering the ground was distinctly different from that already in the water table. Specifically, it had a T:H at least thirty times that of the ground water. This, then, provided a means for distinguishing surface from ground water.

The amount of rain which fell in March 1954 was used in this calculation. Four rain periods

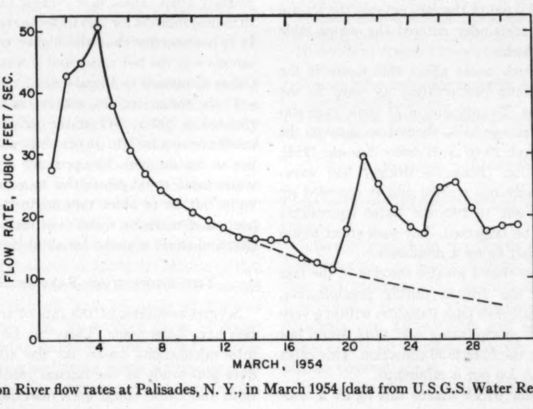

FIG. 4 – Hudson River flow rates at Palisades, N. Y., in March 1954 [data from U.S.G.S. Water Resources Branch]

TABLE 6 – *Data on Hudson Watershed precipitation and tritium content*

Rain	March, 1954	T:H × 10^{18}	Precipitation
			cm
1	13–15	1240	1.28
2	19–20	255	2.09
3	25–26	243	1.35

occurred following the uncontaminated March 3 precipitation and preceding the river sampling. The last of these coincided with the collection and will be neglected. Twenty-three stations were used to derive the precipitation data for the drainage area (U.S. Weather Bureau, 1954). The pertinent information is shown in Table 6 together with the Lamont tritium assays.

The weighted mean T:H for the three rains is 519×10^{18}. From the New York City watershed data (see Table 2 and *Kaufman* and *Libby* [1954]), it is assumed that the normal T:H of the Hudson is 7×10^{-18}. The calculation is not very sensitive to this figure. The tritium concentration of the Hudson was raised to 28.8 by the three rains. The fraction f of the River runoff which is from those rains can be found: $7(1 - f) + 519f = 28.8$, therefore $f = 0.043$.

The total discharge of the Hudson River at Palisades (U.S.G.S. Water Resources Branch, 1954 unpublished data) in terms of the average depth over the whole drainage basin was 3.90 cm for this period. The portion of the discharge which was new water was, therefore, 0.17 cm. Since the total precipitation with increased radioactivity was 4.72 cm, 3.6 pct of the rain entered the stream directly. The remainder entered the water table or re-evaporated.

A factor which could affect this figure is the retention of some precipitation as snow in the mountain areas. Twenty out of 21 snow gage stations in the drainage basin showed no snow on the ground on March 28 [*U.S. Weather Bureau*, 1954]. Only one station (Bennetts Bridge) had snow. Since this is only one station and it recorded six inches (about one to two cm water equivalent) the effect will be neglected. Any such effect would make the 3.6 pct figure a minimum.

It is probable that a greater fraction of the rain was entering the stream during precipitation. This water would flow past Palisades within a very few days after precipitating and thus would not be recorded by the March 30 collection. This effect also makes the 3.6 pct a minimum.

Another factor which makes this figure a minimum involves runoff to lakes. To the extent that the lakes then supply the Hudson, the outflow would be diluted by the older lake water. This effect is small for the Hudson.

Tecolote tunnel—The Tecolote tunnel was built to carry water from the Santa Ynez Valley to the Pacific Coast at Goleta in Southern California. During its construction considerable water was encountered which increased rather regularly in temperature from both ends toward the center of the tunnel. Temperatures as high as 117°F were encountered.

It was decided to sample both the hot water and the cooler water for tritium. R. E. Trefzger of the U.S. Bureau of Reclamation supplied the samples and the temperature data. The object of the analyses was to determine the source of the water and to set limits on the relative amounts of meteoric and juvenile water. The tunnel was cut through moderately to steeply south-dipping Cretaceous and Tertiary siltstones, sandstones, and conglomerates. These strata are cut by several reverse faults.

It will be assumed that the mean natural tritium content of the rain in the area is 4×10^{-18} (based on the one Santa Barbara rain of von Buttlar and Libby). The Pacific Ocean rains discussed earlier [*von Buttlar* and *Libby*, 1955] average about 0.8×10^{-18}. Thus, if anything, the rain estimate is high. The two tritium concentrations are 16.5 and 75.4 respectively in these units. It is only during the spring and summer of 1954 that such values could be achieved, since the samples were collected in January 1955. Thus, it is evident that it took less than nine months for this water to reach the tunnel. It is noteworthy that the higher tritium content sample was the hot water and it was flowing faster (50 as compared to 10 gal/min).

If the mean tritium content of the rain is estimated as 200×10^{18} for the period involved, rain could account for 6 to 31 pct of the sample (depending on the sample). The presence of a pre-existing water table could dilute this rain to the observed value but be of older rain origin itself. Thus the portion of meteoric water is at least 31 pct in one case and could account for all of the water.

THE PRODUCTION RATE OF TRITIUM

Several estimates of the rate of tritium production have been made. These can be broken down into calculations based on the cosmic-ray flux data plus study of the nuclear reaction cross sections and those based on a material balance of a

TABLE 7 – *Production rate of tritium based on cosmic-ray flux and nuclear cross sections*

[a] Details of calculation in *Giletti* [1957].

portion of the Earth's surface. Tables 7 and 8 summarize these estimates. It is evident that the predicted rates of production from cosmic-ray calculations are lower than the rates calculated from the budget data by as much as a factor of ten. The rate calculated in this paper was arrived at in the following manner.

The budget in the North Atlantic Ocean was calculated for the North Atlantic Surface Water (the pertinent data are in Table 9). Mixing of this water was shown to be rapid down to the seasonal thermocline which will be taken as 50 m. The loss of tritium from this 50 m thick layer of water occurs via sinking, radioactive decay, and evaporation. The sinking and decay terms are readily computed (see Table 9). The evaporation term is combined with the precipitation and exchange terms below.

Influx of tritium to the North Atlantic occurs from streams, the South Atlantic, and precipitation and exchange. The amount of tritium from land runoff is small. It was calculated from data of *Kaufman* and *Libby* [1954] and *von Buttlar* and *Libby* [1955] on Mississippi River and European stream concentrations.

It is assumed that equal amounts of tritium are added to the North Atlantic and to the South Atlantic via precipitation and exchange. If the mean residence time of a water molecule in each of the two surface layers (north and south) is taken as ten years, it is possible to derive the tritium concentration of the South Atlantic surface. This calculation yields a natural T:H = 0.6×10^{-18}. This value is used as the tritium concentration of the 6×10^6 m^3/sec of water [*Sverdrup* and others, 1942] entering the North Atlantic from the south.

It was assumed that about 50 pct of the tritium which fell on North America re-evaporated and entered the ocean by precipitation or exchange. This means that only two-thirds of the new tritium entering the North Atlantic was produced over the North Atlantic. Part came from the continent. Thus, while 1.2×10^{25} H^3 atoms enter the North Atlantic annually, only 0.8×10^{25} are produced over the North Atlantic. This yields a net flux of 0.6 ± 0.3 H^3/cm^2/sec.

The actual production rate is larger than this value because about 60 per cent of the production occurs above the tropopause. The half-time of transfer downward across the tropopause is taken as six years [*Stewart* and others, 1955; *Libby*, 1956]. This delay means that some tritium decays in the stratosphere (about 20 pct of the total produced). The net tritium production becomes 0.75 H^3 atoms/cm^2/sec. A detailed calculation is given in *Giletti* [1957].

This critical assumptions in this calculation are that the North Atlantic is large enough to be representative of the Earth and that the 1953 data represent a water system uncontaminated by man-made tritium. These are currently being studied further. It is noteworthy that *Craig's* [1957] calculation based on a continental budget gives 1.2 H^3 atoms/cm^2/sec. A recent calculation by *Begemann* and *Libby* [1957] using a continental balance yields a rate of 2 H^3 atoms/cm^2/sec.

It is possible that a new source of tritium may have to be sought if the budget calculations are right. The error in the present budget computation almost overlaps the theoretical values, but the other authors' values are somewhat too large for this.

The total tritium inventory was calculated based on the following data. A tritium concentration of 1.0×10^{-18} was assumed for the upper 50m in the oceans. Another layer of T:H = 0.2×10^{-18} was assumed from 50m to 200m depth. The resulting weight of tritium for 3.6×10^8 km^2 is 9.6 kg. Allowing for ground-water storage and the small atmospheric tritium reservoir, the total tritium inventory was probably about 12 kg. Since the surface ocean T:H doubled in 1954, the inventory has also doubled.

SUMMARY AND CONCLUSIONS

The initial objective of this study was the establishment of rates of circulation of ocean water masses. It soon became apparent that a more extensive survey was required; one which encompassed the lands and the atmosphere. As a result of the study the following conclusions are drawn:

(1) A steady-state analysis of tritium in natural waters is no longer possible. The total amount of natural tritium on the planet before 1954 was about 12 kg. This inventory has at least doubled since 1954 as a result of thermonuclear tests by the United States and other governments.

(2) Precipitation showed the greatest effects of thermonuclear activity, with the Lamont T:H values changing from a mean of 8×10^{-18} in normal times to 1240×10^{-18} at the peak time in the test series. Following the tests, the maximum half-time of washout from the troposphere was found to be 35 days. The new base level was about 19×10^{-18} and this increase over the previous value of 8 may be due to slow downward exchange of extra tritium from the stratosphere.

(3) The pre-thermonuclear-age tritium concentration of surface ocean waters has been shown by this study to be 1.0×10^{-18}. This value is important to all subsequent work in tritium concentrations since it represents the natural level.

(4) The ocean surface in 1954 had a T:H = 1.9×10^{-18} and probably reached 2.0 after all the debris had come out of the troposphere. Thus the value for the surface ocean doubled.

(5) The surface ocean water mixes down to the seasonal thermocline in one year, but the distribution is patchy and several years are probably required to smooth this out.

(6) The North Atlantic Central Water appears to be 25 years old off the coast of Portugal and in the southwestern North Atlantic. This is based on a mass flow principle with the convergence at about 40° N in the western Atlantic. If lateral mixing is the dominant effect, then the upper portion of this water has a mean age of 25 years and an equivalent of $<2 \times 10^6$ m^3/sec is transmitted downward at the convergence.

(7) Three samples collected at the bottom in the North Atlantic showed measurable tritium. It is possible that some surface water sinks at high

latitudes and flows rapidly along the bottom without mixing completely.

(8) The tritium contents of European rains and streams in August 1954 are of the same order of magnitude as in the United States for comparable latitude.

(9) The rather hot waters in the Tecolote Tunnel were observed to be less than nine months old, showing that the steeply dipping strata plus the various faults permit rapid flow once drainage is started.

(10) Lakes and streams in the United States and Europe were quick to reflect the increased tritium content of rains in 1954. Marked increases were observed within two weeks after the first 'hot' rains. However, the surface runoff still accounted for the major portion of the contamination carried by the streams. The capacity of the reservoir of surface water determined the extent of the contamination. Small reservoirs reacted with much higher T:H values.

(11) The direct runoff of precipitation from the ground surfact to streams was $\geq$ 3 pct for the Hudson River basin in 1954.

(12) A calculation of the cosmic-ray production of tritium was made using the Atlantic Ocean as the reservoir on which the material balance was made. The production is assumed to occur both above and below the tropopause with 40 pct occurring below. A half-time of removal from the stratosphere of six years is chosen. The production is calculated as 0.75 ± 0.4 T atoms/sec cm^2 of Earth's surface. The influx to the sea is 0.6 T atoms/sec cm^2 and the remainder is accounted for by decay in the stratosphere. This is somewhat higher than previous estimates based on known cosmic-ray reactions.

Acknowledgments—The oceanographic samples were collected from the Columbia University research vessel VEMA under the supervision of Maurice Ewing, Bruce Heezen, and Robert Gerard. European continental and coastal samples were collected by D. Carder. Funds for the major part of this research were supplied by the Air Force Cambridge Research Center under contract AF19(604)851 and by the Oceanography Section of the International Geophysical Year.

The senior author acknowledges the considerable help in the early stages of this study afforded him by Willard F. Libby and Sheldon Kaufman formerly at the University of Chicago. Technical assistance was rendered by the Misses C. Dolph and A. Primack, and M. Gwinner, R. Horstmann, R. Janes, R. Lupton, F. Sanson, R. Slane, D. Smith, and W. Taminga. The deuterium analyses were supervised by Wayne Ault.

Submitted in partial fulfillment of the requirements for the Degree of Doctor of Philosophy in the Faculty of Pure Science, Columbia University by B. J. Giletti.

Distortion in Continental Triangulation

CHARLES A. WHITTEN

Abstract—**The present network of triangulation in the United States is the result of adding individual surveys season by season to the existing framework. The last major readjustment of the national net was in 1927. The skeleton framework of that date is now covered by crisscrossing arcs and area nets of first- and modified second-order triangulation. When each survey is mathematically adjusted to be consistent with the previously adjusted surveys, small twists and strains are introduced. These tend to accumulate through successive adjustments to a point where observations are distorted far beyond normal expected errors. Efforts are made to keep this distortion to a minimum by increasing standards of accuracy for the basic framework and by planning surveys to give strength to the net as well as furnishing desired information for engineering and scientific projects. Methods of computation which will give complete information on internal accuracy and checks must be used. Also, through the application of modern electronic computing equipment, it is possible to adjust the maximum size net, thereby reducing probability of extreme distortion.**

A basic requirement for the construction of most large-scale engineering projects is a complete set of plans or master drawings on which all details of every phase of the project have been illustrated. These are needed before any construction can be undertaken. If the engineering project also has a scientific use, volumes of additional specifications and descriptive material will be provided in advance. This is just normal procedure.

Now, let us consider briefly the development of an engineering structure for which there have been no detailed preliminary plans for the entire project. The building-up of a continental network of triangulation is analogous to this. In such a network individual surveys are connected to each other in a manner to permit continuous computation. Rigid specifications must be followed in the execution of each survey. This is similar to a requirement that the material used in a structure must meet certain standards. However, when the urgency of related engineering activities hastens the mathematical adjustment of these individual surveys, the result is a network that is of piecemeal construction rather than one that is completely homogeneous.

Since we have compared a network of triangulation to an engineering structure we must also use an engineering approach insofar as possible, in the development of it. The progress that has been made in the last hundred years is remarkable. Our predecessors were very practical in their treatment of the accumulated survey data, and the history of the horizontal-control datums in North America is well known. However, in the past each generation seemed to be faced with a fundamental problem of fitting new surveys to the then existing net. This same problem faces us today. It is the normal consequence of attempting to make a large structure rigid by adding one member at a time to it.

The early surveys in this country consisted of arcs of triangulation crisscrossing each other to form loops 50 to 60 mi on a side. These loops are now being filled with networks of single triangles covering the area. The area networks are very strong in a mathematical sense and frequently when they are adjusted into the previously adjusted loops, excessive corrections are placed on the original observations for the mere requirement of computational consistency throughout the net. This distortion is caused by systematic weaknesses in the control framework. The magnitude of the distortion in the area net depends upon the distortion that exists in the framework. Let us compare the situation to a watch crystal. If the frame has been damaged or squeezed out of shape by even an infinitesimal amount, there is no way to fit the crystal, and any attempt to do so will surely fracture it. The solution is to repair the frame.

That, very simply, is our problem today. The fundamental framework in sections of the country has become slightly deformed through this process of adding survey to survey. The error in geographic position is not significant and cannot be detected on any map. However, the errors in azimuth or length of individual lines are large enough to be detected and even be disturbing to the users of control data.

This problem must be resolved. One solution would be a total and simultaneous readjustment of all surveys. Personally, I would not recommend such a project until the network has been fully completed. Our present approach for a workable solution to the problem is based on three major guide lines.

First, the fundamental framework must be able to meet all standards of accuracy. Experience has shown us that if any portion of a first-order arc has scale errors approaching 1 part in 25,000, the adjustment of adjacent networks will be totally unsatisfactory [*Whitten*, 1957]. Therefore, the minimum standard of accuracy for first-order triangulation was recently raised to 1 part in 50,000. Most of our continental framework meets this higher standard, and when it is known that a portion of it falls below the minimum requirement, the original survey is strengthened.

This strengthening operation brings us to our second guide line. The development of instruments for measuring base lines electronically with either light or radio waves has provided us with a means of correcting these errors of scale. Base lines may be easily inserted into the older surveys and, through recomputation, the lengths of lines in the original survey will have the required accuracy.

The problem is more involved than that. Merely adding a base line and correcting one line in an arc of triangulation may produce further distortion. An arc is fixed in over-all length by the latitudes and longitudes of the end points. This then fixes the over-all scale. If we correct some of the lengths in an arc by a positive amount, other lengths in the same arc must be shortened in order to maintain the fixed over-all length. Generally, it is necessary to 'relax' these fixed end points and readjust a fairly large system of crisscrossing arcs so that the distribution of the changes in scale will not create any further abnormal distortion.

The methods to be used in these major readjustments also require guides. Here again, we can use electronic tools. Modern high-speed computers can be used to test the adequacy of a proposed readjustment. Internal checks built into a computer program provide the means of determining the accuracy of the adjusted values. Closures of azimuth, length, latitude, and longitude may be obtained directly from the solution of a set of normal equations which have been formed from a series of observation equations, using the classical method of adjusting by the variation of coordinates, and to which have been added the proper condition equations containing the true closures of these external controls. This special technique of combining the two types of equations was first described by Helmert and, in more recent times, by *Stearn and Braaten* [1948]. The use of this technique, with the further adoption of the Cholesky method for solving normal equations, presented the programmers of the high-speed computer with a special problem of handling complex numbers. This was only one of many tricky processes for which machine codes and instructions were needed. The application of electronic computers to geodetic problems has broadened the mathematical experience and knowledge needed for the development of our basic network.

In conclusion I wish to state again that it has been the urgent need for adjusted results of individual surveys that has been responsible for the lack of homogeneity in the continental network. Through our efforts to be practical in furnishing data as soon as possible we have lost some of the over-all strength that might have been obtained if this urgency had not existed. In the years immediately ahead of us we will find it necessary to revise portions of the federal net for these reasons that I have described. Naturally, there will be considerable inconvenience to engineers who have used control data with the confident belief that the coordinates would not be changed. I hope that they will overlook this inconvenience and recognize that they will be using values which are more accurate and also rigorously connected to a stronger continental network.

Geodetic Control in Jungle Areas

CARL I. ASLAKSON

Abstract—Oil companies are frequently faced with the problem of delineating oil concession boundaries in unmapped areas. Such boundaries are often defined by latitude and longitude lines drawn on outline maps. Usually, time limits are set for defining the concession boundaries which preclude the use of conventional surveying techniques. This paper describes the manner in which Aero Service Corporation employed shoran trilateration and shoran controlled photography for geodetic control in the Peten area of northern Guatemala. This method is commonly known as the SCP or secondary control point method.

One of the difficult problems facing oil companies is the physical demarcation of concession areas. Frequently, many companies are granted concessions in unsurveyed countries. Often, such concessions are defined by lines drawn on maps which are little better than outline maps. This was the problem which 15 oil companies faced in Guatemala in 1956. Figure 1 shows the Peten region in northern Guatemala. No geodetic control existed in the entire region, the greater part of which was almost impenetrable jungle. The concession agreements specified detailed boundary surveys and the time allotted for the survey was brief. Hence, the problem consisted of: (1) providing the necessary geodetic control to serve as initial survey points; (2) meeting time limits specified in the concession agreements; (3) satisfying the Guatemalan government and the concessionaires as to the accuracy of the resulting control.

In addition to the above requirements an airborne magnetometer survey was to be made over the entire Peten area. The Peten region had previously been photographed. However, because of the lack of control, no mosaic could be compiled. Owing to time limitations, no consideration could be given to conventional control methods. The possible existence of deflections of considerable magnitude precluded the use of astronomic positioning. Hence, it became necessary to employ shoran trilateration combined with shoran secondary control points, commonly referred to as SCP's. This was the project undertaken by Aero Service Corporation. The aircraft used was a DC-3 flown to Guatemala after the instrumentation had been installed in the United States. H. Meier was the geodetic engineer in charge of the technical direction.

SCP's or shoran secondary control points in the Bahama Islands—The writer first began development of the technique of establishing ground geodetic control by means of shoran controlled photography at Denver, Colorado in 1946. This technique was first used extensively in 1949 to 1951 in the Bahama Islands during the Air Force Missile Test Center Hiran Survey. Figure 2 indicates numerous islands which were positioned by this method. Obviously, it would have been uneconomical to establish main scheme Hiran stations on all the islands shown.

The SCP method—Briefly, the SCP method consists of selecting the point to be positioned, flying across the point in four directions with the cameras operating at minimum exposure interval with shoran operating during these flights, the shoran recorder being synchronized with the photogrammetric camera. A plot of typical SCP flights is shown in Figure 3. The coordinates are the computed plane coordinates of the principal points of each photograph. These relative positions are computed from the shoran data. Figure 4 shows a typical SCP photograph. Note that the point circled is a small clearing in the jungle, within which a point is marked with a white cross made with lime. Figure 5 is one of these photographs with the clearing area enlarged to show the cross. It should be noted that the SCP flights are made with flight headings in four directions, thus increasing the probability that tip and tilt errors are minimized in the final position.

Computing the SCP—The steps in obtaining the SCP position are: (1) Prepare a graphical plane coordinate plot of the computed positions at the mean scale of the photographs (Fig. 3). (2) Mark the selected SCP point and principal point on each photograph. (3) Scale the distances from the principal points to the SCP. (4) Plot an approximate position of the SCP on the plane coordinate plot. (5) Make a simple least-square adjustment to cause all scaled distances to converge at the same point. The constant term in each observation equation is the difference between the computed lengths to the

assumed position and the lengths as scaled on the photographs. (6) Convert the adjusted plane coordinate position to geodetic coordinates. Note that the final SCP position is dependent on the use of shoran coordinates measured with respect to one pair of control stations.

Control stations for Peten SCP's—Figure 6 shows the control stations from which all the Peten SCP's were located. Stations Huehue, Coban, and Izabal were first-order triangulation stations on the same arc. Belice was a British Honduras station on a separate datum for which an approximate datum tie had been made. It was necessary to verify this datum tie and also to establish a fifth control station, Buena Vista. Hence, all distances shown in Figure 6 were measured by the shoran line-crossing technique and the trilateration net was computed. The longest line was from Huehue to Belice and was over 196 mi. in length. The uncertainty of the datum tie at Belice had been given as ±20 ft. Inasmuch as the shoran trilateration position of this point agreed with the approximate position by 18 ft., the position as given in the approximate datum tie was held in the adjustment. The six known distances thus afforded an excellent means of obtaining an absolute calibration of the shoran distances. This calibration was applied to all SCP measurements. It showed the characteristic change with distance attributable to normal signal strength attenuation. The final distribution of the SCP's is shown in Figure 1.

Altitude control—Absolute altitudes as well as differential heights are required for SCP and shoran reductions. Calibrated pressure altimeters, radio altimeters, and airborne psychrometric measurements were used in obtaining accurate altitudes. The radio altimeter was calibrated at San José Airport against photogrammetric heights. The corrections were found to be a function of height above terrain and were of considerable magnitude. This effect was predicted inasmuch as the correction is a function of signal strength. By a number of flights between sea level and check surfaces in the heart of the Peten area, the altitude of the check surfaces was well established. These check surface flights were made by flying at a constant pressure

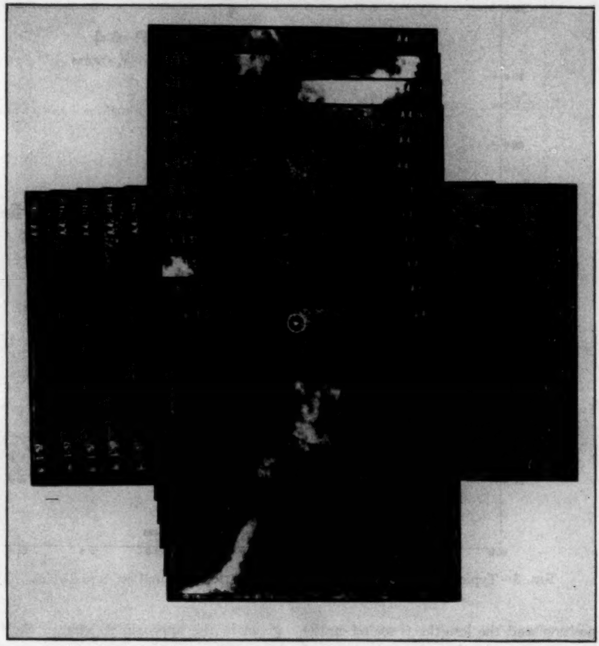

FIG. 4 – One series of overlapping photos made during secondary control point flight in El Peten area; two such series are required per flight to minimize aircraft tip and tilt errors; circled point shows jungle clearing and SCP cross

level, obtaining psychrometric data on the flight, computing the slope of the isobaric surface and applying this correction as well as the radio altimeter height differences. After the check surfaces were established, they, in turn, served in a similar manner for determining absolute altitudes of the SCP and trilateration flying heights.

Time required for project—Although the entire project required slightly less than four months, the geodetic control phase required only 38 days, the remainder of the time being devoted to magnetometer surveys. Thus, the establishing of basic control for an area of about 12,000 sq. mi. was slightly more than one month.

Accuracy of SCP's—A complete evaluation of SCP position accuracy has never been made. The internal consistency as revealed from computations is very high, seldom exceeding ±10 ft for the probable position error. This is with respect to the two control stations used and, of course, is not a realistic measure of error. On two occasions, SCP positions have later been verified by triangulation. In one case, the resultant position error was 40 ft and in the second case, it was 100 ft. The accuracy is such that SCP's serve as excellent control for 1:50,000 mosaics using radial plotting methods. This accuracy could be improved by flying the same SCP from a second pair of stations and adjusting the position from all four stations.

Conclusions—Shoran SCP's provide a valuable means of rapidly extending lower-order control over areas difficult of access such as jungle areas.

SHORAN TRILATERATION NET

Fig. 6 – Shoran station locations and trilateration net employed for determination of secondary control points during Guatemalan survey

Recently, Aero Service Corporation completed an extensive SCP project in the Arabian desert. Whenever large areas have been photographed but no control is available, shoran SCP's provide the most rapid method presently known for obtaining the control. This technique is of great value to oil companies who are granted foreign concessions, the physical boundaries of which are defined on inadequate maps.

Airborne Measurements of Atmospheric Electricity

J. H. KRAAKEVIK AND JOHN F. CLARK

Abstract—An experimental investigation of the variations of atmospheric electric quantities in space and time was conducted. A review of past measurements reveals several inaccuracies and inconsistencies which stimulated the investigation. The simultaneous measurement of both polar conductivities, of potential gradient, and of several meteorological quantities from a multi-engine airplane, and the derivation of other atmospheric electric variables, are described. Altitude 'profiles' of conductivity and potential gradient up to 6 km obtained on a representative sounding over the Chesapeake Bay show a secondary exchange layer above the more common surface exchange layer. The space-charge density profile exhibits positive charge concentrations at the tops of these layers, near the bases of the associated temperature inversions. Upward convection of positive space charge causes the computed conduction-current density within the exchange layers to be some 40 pct higher than its relatively constant value above the layers. The product of columnar resistance and current density, employed by previous workers to obtain atmospheric potential, provides erroneous values whether the conduction current near the Earth's surface or the average value over the entire altitude range is used. On the basis of a 6-km atmospheric potential of 327 kv obtained from the integrated potential gradient, the true extrapolated total potential of the high atmosphere is 341 kv at a time near the diurnal maximum.

Introduction—After it was discovered in the 18th century that the Earth possesses a negative charge during fair weather, and that the atmosphere is an imperfect insulator, one of the basic questions of atmospheric electricity was raised: How is the Earth supplied with negative charge to compensate for the loss of charge caused by atmospheric conduction? During the past fifty years, measurements of potential gradient and atmospheric conductivity have been made primarily on land surfaces of the Earth, with occasional observations over the oceans and in the Arctic. From this vast body of statistical data [*Whipple*, 1929], together with aircraft measurements [*Gish* and *Wait*, 1950], the basic problem of atmospheric electricity has been rather convincingly solved: Negative charge is carried to the Earth by lightning and point discharge from trees and other high objects during thunderstorms. The airborne measurements have also provided some information on the vertical distribution of atmospheric electric variables.

Accepted views of the fair-weather electrical properties of the atmosphere prior to the present investigation may be summarized as follows: The negative Earth and positive high atmosphere may be regarded as a spherical condenser, according to *Gish* [1951], with the atmosphere a leaky dielectric of some 200 ohms resistance. This atmospheric condenser is kept charged to a potential of approximately 360 kv by world-wide thunderstorm activity, which supplies the condenser with some 1800 amp continuously to maintain equilibrium. The stability of the potential is uncertain, although on the average it varies diurnally by nearly 20 pct about the mean. The conductivity of the atmosphere is not uniform but increases almost exponentially with altitude from its average ocean surface value of 2.5×10^{-14} mho/m [*Chalmers*, 1949; *Gish*, 1944]. Consequently the potential gradient exhibits an almost corresponding decrease with altitude from its average surface value of 130 v/m. This results in a positive atmospheric space charge which decreases with altitude [*Gish*, 1949]. The conduction current density, which is the product of conductivity and potential gradient, has an average ocean surface value of 3.2×10^{-12} amp/m², but shows a tendency to decrease slightly with altitude [*Everling* and *Wigand*, 1921]. Surface atmospheric electric measurements, usually made within the turbulent and frequently contaminated surface exchange layer, are subject to local variations due to weather and pollution, which mask the variation in atmospheric potential caused by world-wide thunderstorm activity.

Although the general features of the atmosphere's electrical properties are understood, there remain a number of detailed discrepancies. For example, altitude distributions of potential gradient have been obtained from balloons but these are inaccurate, according to *Schonland* [1953], owing to "the distortion of the field by free and induced charges on the balloon." From these inaccurate balloon measurements estimates of the total atmospheric potential have been made by integrating the potential-gradient distributions.

A second method which has been used for estimating the total potential is to measure the conductivity distribution with altitude and from it obtain the total columnar resistance (resistance of a column of air 1 m^2 in cross section extending from the Earth to the high atmosphere). During the time conductivity is measured at altitude, the current density is measured at the Earth's surface. If the current density is assumed to be the same at all higher altitudes, the total potential is equal to the product of the columnar resistance and average current density. These estimates of total potential vary from 200 to 400 kv, according to *Gish* [1949].

As a second related example, the condition of quasistatic equilibrium in the atmosphere requires the vertical current density to be constant with altitude in fair weather. However, the only simultaneous airborne measurements of conductivity and potential gradient [*Everling* and *Wigand*, 1921] provide a current density which decreases with altitude.

Most past measurements of atmospheric electric variables have been made from the Earth's surface, where statistical analysis of large amounts of data is required to extract the descriptive features of atmospheric electricity. It is the purpose of this paper to show how the conductivity and potential gradient are obtained directly by means of an airplane, and used to derive the columnar resistance, current density, atmospheric potential, and space charge density, up to altitudes well above the surface exchange layer; and to present experimental altitude distributions of these quantities representative of the atmosphere over the Eastern United States.

Measurement techniques—Although its altitude capability is much less than that of balloons and rockets, the airplane was chosen as the research vehicle for a number of compensating reasons. First, according to *Gish* [1949], more than 80 pct of the total atmospheric potential lies below the ceiling of the aircraft (6 km), and that portion inaccessible to measurement is fairly predictable because the conductivity of clear air does not vary appreciably with time at high altitudes. The airplane is more accurate than the balloon in the measurement of ambient potential gradient, because its conducting skin and geometrically-invariant configuration can be permanently calibrated for electric field distortion. It provides the most precise control of position and altitude, the best chance of using the same instruments for repeated measurements, and the best facilities for an observer to accompany his instruments. Furthermore it has a relatively large space and weight capacity, and can be used both for transportation and as a research vehicle at almost any point on the Earth.

In this study each vertical 'sounding' of the atmospheric electric variables is made over a fixed geographic locality. Data are taken in steps during descent from the airplane's ceiling (6 km), with the aircraft maintaining constant heading and speed for several minutes at each altitude. An entire sounding requires approximately 70 min. Each sounding is taken in fair weather, in which the maximum cloud cover at any altitude is 10 pct, and there is no precipitation within 50 km.

A P4Y airplane was instrumented as a mobile laboratory (see Fig. 1) to measure and record continuously both polar conductivities, potential gradient, aircraft charge, and atmospheric temperature, pressure and relative humidity. Three visual recorders provide up to twelve synchronized channels of data. Time checks, geographic locations, weather summaries, and all adjustments of either the research instrumentation or the aircraft operating conditions are reproduced by means of an aural recorder.

The atmospheric polar conductivities are measured simultaneously by means of two Gerdien-type cylindrical condensers, through which air flows continuously. The accelerating voltage is applied to the outer cylinder of each condenser while the ion current to the central electrode is measured with a vibrating-reed electrometer. Calculations and airborne measurements both demonstrate that the conductivity meters are always operated on the linear portion of their current-voltage characteristics. Each polar conductivity is obtained from the difference in measured current for two separate accelerating voltages. It was also verified experimentally that the measurement of conductivity, which is accurate to within 5 pct, is not influenced by the charge normally residing on the airplane during fair weather [*Kraakevik*, 1958]. The total conductivity λ is the sum of the positive and negative conductivities.

In fair weather the positive atmospheric potential gradient $\partial V/\partial Z$ is vertical and is numerically equal to the negative electric field E. These quantities are measured with three grounded-rotor induction-type electric field meters located at the

bottom of the aircraft fuselage and at each wing tip facing outward. Three independent quantities are derived from these field meters: E_y, the field component along the wing axis; E_z, the component perpendicular to the wing and fuselage axes; and the airplane charge. The vertical fair-weather potential gradient is obtained from E_z during straight and level flight, and from E_y during 30° precision banks of the airplane. These measurements have been corrected for the electric field distortion of the aircraft itself by comparing observed values of potential gradient and conductivity on the ground and from the airplane during low-altitude flights over a portable surface station. The absolute accuracy of each airborne potential gradient measurement is within 10 pct [*Clark*, 1957].

Within the exchange layer, the altitude distribution of atmospheric electric variables is often qualitatively determined by meteorological factors. Therefore the aircraft was also instrumented to measure temperature, pressure, and relative humidity, using an experimental aerograph developed at the U. S. Naval Research Laboratory. Temperature is measured with a vortex thermometer which is operated on the principle of cooling the air by rotation to compensate exactly for the ram heating. This method provides free-air temperature nearly independent of air speed over a wide range [*Ruskin*, 1954]. A cylindrical carbon hygrometric element surrounding the thermometer measures the relative humidity. The pressure is obtained from the aircraft static pressure system.

Fig. 2 – Altitude distribution of conductivity

Experimental results—On May 24, 1956 at 18h 00m GMT a sounding was taken over the Chesapeake Bay. The weather was dominated by a high-pressure area centered over the Great Lakes. In the Bay area there were scattered cumulus clouds at an altitude of about 1.2 km and some high scattered clouds above 6 km. The wind was from the north.

The altitude distribution or 'profile' of conductivity is plotted on a semilogarithmic scale in Figure 2. Up to 1.2 km the conductivity is low and variable, undoubtedly owing to a large number of aerosols, which are mixed because of turbulence throughout the surface exchange layer. At the top of the surface exchange layer (just above 1.2 km), where there is a temperature inversion, an abrupt increase in λ occurs. This is in agreement with the results of *Sagalyn* and *Faucher* [1954] over New England.

A rather uncommon feature of overland profiles is the secondary exchange layer from about 1.3 to 2.3 km. Above 3 km the conductivity shows an exponential increase with altitude. It is apparent that the conductivity profile obtained in the contaminated air above the Chesapeake Bay departs considerably from the simple exponential distribution obtained in the relatively clean air above Greenland [*Kraakevik*, 1958]. The ratio of negative to positive conductivity above the two exchange layers is 1.1, in agreement with that obtained in Greenland.

The corresponding potential-gradient profile is shown in Figure 3. This curve is almost a reflection of the conductivity distribution, with abrupt decreases in potential gradient just above 1.2 and 2.1 km corresponding to increases in conductivity at the same altitudes. However, in contrast to the variable conductivity, there is a smooth decrease in potential gradient with altitude in the surface exchange layer, necessarily due to the presence of a positive space charge. Above 3 km the measured values of potential gradient depart from the smooth exponential curve by less than 10 pct.

Other atmospheric electric variables may be derived from the measured values of conductivity and potential gradient. The conduction current density j is obtained from

$$j = \lambda E \qquad (1)$$

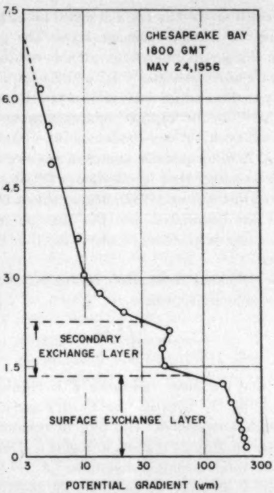

FIG. 3 – Altitude distribution of potential gradient

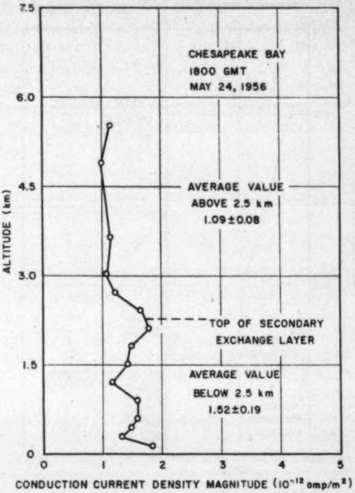

FIG. 4 – Conduction-current density profile

and consequently is negative in fair weather. A plot of conduction current density against altitude is given in Figure 4. Above 2.5 km j is almost constant with altitude, having an average value of -1.09×10^{-12} amp/m², with a standard deviation of only 7 pct. This is in agreement with the classical view [*Chalmers*, 1949], in which the conduction current density is assumed constant with altitude.

Figure 4 shows that within the exchange layers j is higher on the average and more variable than above the layers. This can be explained by the presence of a convection current density j_c, where

$$j_t = j + j_c \tag{2}$$

and j_t is the total current density. The mechanical upward transport of positive space charge results in a convection current of opposite polarity from the conduction current. Thus in order to maintain the total current sensibly constant, j becomes more negative, having an average value of -1.52×10^{-12} amp/m² ± 13 pct within the exchange layers. If it is assumed that j_t is constant with height over the entire altitude range, and equal to the average value of j above 2.5 km, then an average convection current density of $+0.43 \times 10^{-12}$ amp/m² below 2.5 km is obtained. It is evident that within the exchange layers the convection current can at times be an appreciable fraction (for example, 40 pct) of the total current.

Space-charge density is obtained from the altitude variation in potential gradient. Since the fair-weather potential gradient is vertical, the space-charge density ρ is derived from Poisson's equation, and in mks units is

$$\rho = -\epsilon \frac{\partial^2 V}{\partial Z^2} \tag{3}$$

where ϵ is the atmospheric dielectric constant. This reduces to

$$\rho = -55.2 \frac{\partial^2 V}{\partial Z^2} \tag{4}$$

where ρ is in elementary charges per cm³, and $\partial^2 V/\partial Z^2$ is the rate of change of potential gradient with altitude in v/m², obtained from $\partial V/\partial Z$ by numerical differentiation between experimental points.

Space-charge density and temperature profiles for May 24 are given in Figure 5. The histogram presentation of ρ is used because of the inaccuracies in taking the derivatives of experimental data. The largest positive values of space charge occur at and just below altitudes where there are temperature inversions, which correspond to the tops of the exchange layers. A comparison with

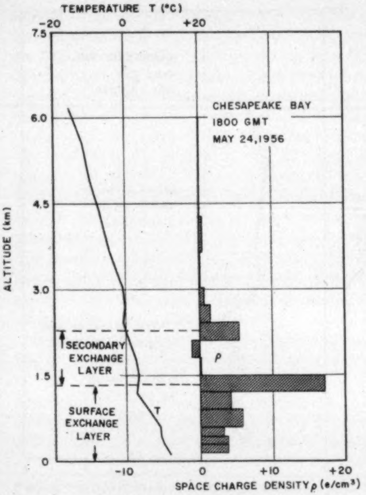

FIG. 5 – Space-charge density and temperature profiles

Figures 2 and 3 shows that changes in conductivity and potential gradient are much more sensitive indicators of tops of exchange layers than changes in temperature gradient.

The classical profile of space charge is one in which ρ decreases monotonically with altitude because of a constant conduction current flowing through a medium of increasing conductivity with height [*Chalmers*, 1949]. Since on May 24 the conductivity does not increase smoothly with altitude within the surface exchange layer (Fig. 2), if charge transport were by conduction alone the equilibrium space-charge density should vary with altitude, having both positive and negative values. However it may be seen in Figure 5 that below 1.2 km ρ is always positive and approximately constant. Thus, mechanical transport of space charge, or convection current, is required to maintain ρ relatively constant with altitude, in agreement with the current density results.

One possible explanation is that a large positive space-charge density exists below the lowest altitude at which measurements were made (150 m). The depletion of negative ions near the Earth's surface and the resulting positive space charge are normal consequences of the 'electrode effect' [*Gish*, 1951]. The positive space charge is then convected upward and is well mixed by turbulence within the surface exchange layer. The positive space-charge accumulations at the conductivity discontinuities just above 1.2 and 2.1 km are due partly to this upward convection of positive charges and partly to the 'capture' by condensation nuclei of small positive ions conducted downward from above. Another possible source of positive charge is the one suggested by ***Mühleisen*** [1956] and reiterated by ***Chalmers*** [1957], that positively charged nuclei are introduced into the atmosphere from combustion and other sources on the Earth's surface.

The columnar resistance r is obtained from the total conductivity, where

$$r = \int_0^Z \frac{dZ}{\lambda} \tag{5}$$

The total columnar resistance R is obtained by integrating (5) between the Earth's surface and the high atmosphere. The plot of columnar resistance on May 24 is given in Figure 6. The value for the total columnar resistance of 24×10^{16} ohm-m² is obtained by assuming the contribution to R above 6 km is the same as that measured by *Woessner*, *Cobb*, and *Gunn* [1958] on a series of balloon flights in the Washington, D.C., area. It is to be noted that the low conductivity within both exchange layers is responsible for 85 pct of R. Between 3 and 6 km the measured conductivity and consequently the incremental columnar resistance are nearly the same as those observed over

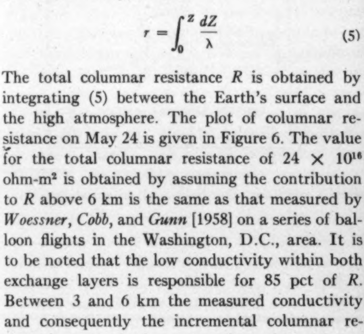

FIG. 6 – Columnar-resistance variation with altitude

Greenland [*Kraakevik*, 1958]. The fact that the columnar resistance over the Chesapeake Bay is more than three times that over Greenland explains the comparatively low value of conduction current at the former location.

The atmospheric potential is derived in two ways. First it is obtained directly by the numerical integration of the potential gradient. This method provides the true atmospheric potential V, which is plotted as a function of altitude in Figure 7. The potential at 6 km is 327 kv. If it is assumed that the exponential decrease in potential gradient between 3 and 6 km plotted in Figure 3 extends upward to the high atmosphere, the total atmospheric potential V_T is 341 kv. These values are considerably higher than the 220 kv 6-km potential and the extrapolated total potential of 283 kv obtained in Greenland by *Clark* [1957]. However, the Greenland potential was obtained at 11h 00m GMT, near the mean of the diurnal variation, and that in Figure 7 at 18h GMT, near the diurnal maximum. From the *Carnegie* 1928–29 ocean-surface potential-gradient results [*Torreson* and others, 1946], V_T at 18h GMT in May is 20 pct higher than that at 11h in September. Applying this correction to Figure 7, the total potential corresponding to 11h GMT for the May 24, 1956, sounding is 284 kv. The agreement between this value and V_T obtained in Greenland is excellent, both being considerably lower than the 360 kv value given by *Gish* [1951].

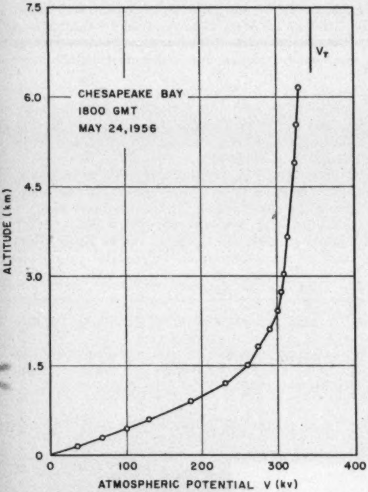

FIG. 7 – Atmospheric-potential variation with altitude

In the second (incorrect) method the atmospheric potential is derived from the average current density $\bar{j}$ and the columnar resistance r. In this case

$$V_j = -\bar{j}r \qquad (6)$$

and for the total potential

$$V_{jT} = -\bar{j}R \qquad (7)$$

Thus the curve in Figure 6, when multiplied by the average j over the 6-km altitude range, gives the variation in V_j with altitude. By way of comparison, V_j at 6 km is only 289 kv, where V is 327 kv. The reason for this discrepancy is that if the average current density of -1.29×10^{-12} amp/m^2 is assumed to be constant over this altitude range, $\bar{j}$ is less negative than the actual conduction current within the exchange layers, which contribute some 85 pct to R. Thus within the exchange layers V_j is too low, particularly at the top. The average current does not provide a compensating increase in V_j above the exchange layers because the contribution to R in this region is small. Another way of looking at it is that space-charge convection generates a current which is not negligible; hence a constant vertical conduction current density may not be validly assumed. If the current density measured at the lowest altitude were the surface value, and were assumed constant over the entire altitude range, then V_j at 6 km would be 411 kv, which is too high. Thus it is risky and in general incorrect to measure current density at one altitude (usually the surface) and compute a potential from an assumed constant current and a measured columnar resistance.

Eq. (7) provides the true potential only when the measured conduction current density is constant over the entire altitude range. In general, the incremental potential over a small altitude range is

$$dV = -j\,dR = -\frac{j}{\lambda}\,dZ = -E\,dZ \qquad (8)$$

and the true potential must be obtained from the measured electric field by integrating (8).

Summary and conclusions—An airplane was instrumented to measure simultaneously both polar conductivities, potential gradient, and several meteorological quantities, in order to study their variations in space and time. Representative altitude 'profiles' of conductivity and potential gradient over the Chesapeake Bay indicate the presence of a secondary exchange layer above the more common surface exchange layer. Above these layers, the total conductivity and the negative to positive conductivity ratio are in good agreement with results obtained previously in clean air over Greenland.

The computed conduction-current density profile over the Chesapeake Bay shows the effects of space-charge convection within the exchange layers. The conduction current density is substantially constant above these layers, having a magnitude of only 1.09 × 10^{-12} amp/m^2, but within the layers it is increased by some 40 pct due to a convection current. The space-charge density profile, derived from the potential-gradient distribution, is dominated by two regions of high positive concentration, one at the top of each exchange layer, near the bases of the associated temperature inversions. Low conductivity within the exchange layers is responsible for 85 pct of the extrapolated total columnar resistance of 24 × 10^{16} ohm m^2.

The extrapolated total atmospheric potential at 18h GMT, near the diurnal maximum, is 341 kv, based on a 6-km potential of 327 kv obtained by integrating the potential gradient. This is 20 pct higher than the total potential over Greenland at 11h GMT obtained previously, in excellent agreement with the average diurnal potential gradient variation measured by the *Carnegie*. The product of columnar resistance and current density, used by previous workers, provides erroneous values of atmospheric potential. These values are too high if the conduction current density near the Earth's surface is used, and too low if the current is averaged over the entire 6-km altitude range of measurement.

Acknowledgments—The authors wish to thank R. E. Bourdeau for his substantial contribution to the electric field meter system and its installation in the aircraft, and for his helpful criticism of the manuscript. Thanks are also due C. R. Hamilton for his contribution in instrumenting the airplane; to G. P. Serbu and R. V. Anderson for their participation in obtaining the flight data; and to J. E. Dinger for the use of the aerograph.

The 27-day Period in United States Temperatures

S. W. VISSER

Abstract—The daily maximum temperature observations in the United States during two series of regular 27-day periods in the years 1947 and 1953 are harmonically analysed. The amplitude being statistically insufficient the reduced amplitude, that is amplitude divided by standard deviation, is introduced. The results arrived at are compared with those in Europe. The investigation discloses the intermediate action of the ionosphere, especially that of the magnetic storms in the F2 layer. We state the following sequence of phenomena in the 27-day period.

Solar activity	Year	Max. day	Magnetic storms F2 layer		Daily maximum temperature					
					Europe		United States			
							West		East	
			Max. day	Min. day	Highest day	Lowest day	Highest day	Lowest day	Highest day	Lowest day
High (R = 165)	1947	13.3	16.2	...	...	...	...	...	...	...
Weak (R = 13)	1953	13.6	...	17.9	...	...	...	...	...	...
High solar activity			...	...	...	21.0	...	22.2	26.9	...
Weak solar activity			...	...	...	19.2	...	22.3	24.9	...

The numerical results are shown in Tables 1 and 2.

This paper contains a comprehensive review of our communication [*Visser*, 1956] on the 27-day period, at the IUGG Assembly, Rome, 1954.

The method—When studying the 27-day period most investigators calculate average values over long time intervals. Yet this method is not quite acceptable because the periodicity is highly irregular: it starts at some unexpected moment, it dies out at another moment and it may be absent during long intervals. When average values are calculated over many years the period fades out or is revealed only poorly. For this reason we have confined our research to well developed regular occurrences of 27-day sunspot periods in which only one maximum and one minimum occur, returning in consecutive periods at about the same time. Such a case occurred during the summer of 1947. Eight well-developed 27-day periods were followed by significant heat waves in central Europe (see *The data* below). This fact led to an investigation of the daily maximum temperatures in Europe and North America. We shall discuss the results for the years 1947 and 1953.

When arranging the sunspot data in rows of 27 days the regularly recurring sunspot waves stand out and it is easy to select them. We have considered the central day of five consecutive days with highest relative sunspot numbers to be the epoch of the maximum.

Concerning the maximum temperatures we have calculated overlapping 27-day means and entered these means at the central day of the matching 27-day intervals. The differences between these mean values and those observed daily provide more or less regular successive positive and negative deviations, revealing the more or less regular occurrence of the period. We have arranged these temperature deviations in such a way that each of the sunspot maxima selected fell on the central day of the row of 27 temperature deviations. Thus we find the behavior of the temperature during 13 days before and 13 days after the sunspot maximum.

The result is accumulative. The influence of each individual sunspot period on the temperature may be weak, but by repeating the method for consecutive periods in quite the same way, the influence becomes more and more obvious when actually present. Therefore more or less periodical systems of 27 numbers are obtained. It is now necessary to test their significance.

For each series of selected recurrences the 27 daily averages both of the sunspot numbers and the maximum temperatures have been calculated and the results harmonically analysed. We have limited this research to the first harmonic. A random series of 27 numbers, however, when harmonically analysed, also may yield some phase angle ϕ, and some amplitude $\mathbf{a}$ and, therefore, we must check the reliability of the harmonics found. To this end we have determined for each of the 27 values obtained the difference observed minus harmonic and calculated the standard deviation σ. We must require that σ be small, or, better, that $\mathbf{a}/\sigma$ be large. This quotient is defined as the reduced amplitude $\mathbf{a}_r$. The reduced amplitude amounted to 4 or more for the sunspots, for the temperatures it was 1.5 and more.

Figure 1 shows the features of the method applied to 12 cases in the years 1947 and 1953.

Figures 1a and 1g show a very close relation between the sunspots and their harmonics both for the years 1947 and 1953. As to the other curves, for $\mathbf{a}_r = 1$ the limiting (dotted) curve reaches

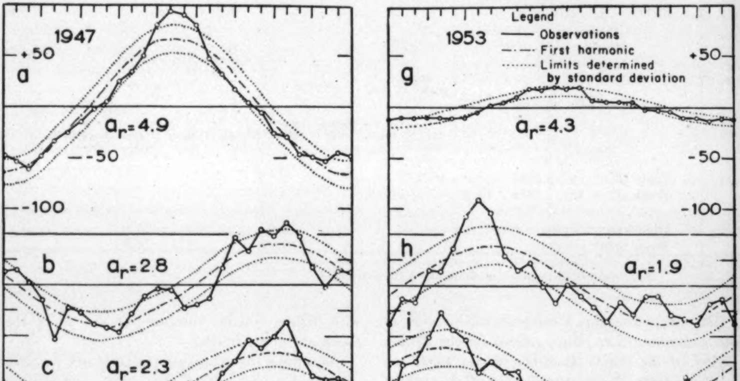

FIG. 1 – The 27-day period in 1947 (a to f): (a) sunspots; maximum daily temperatures at (b) Marburg, Germany; (c) De Bilt, The Netherlands; (d) Susanville, California; (e) Lakeview, Oregon; and (f) Newport, Vermont; 1953 (g to l): (g) sunspots; (h) I-index at De Bilt; maximum daily temperatures at (i) Green River, Utah; (j) Kassel-Harleshausen, Germany; (k) Lakeview, Oregon; and (l) Akron, Ohio; each scale division of the temperature curves represents 2° C, and of the I-index, 4 units; the abscissae represent the 27 days of the period.

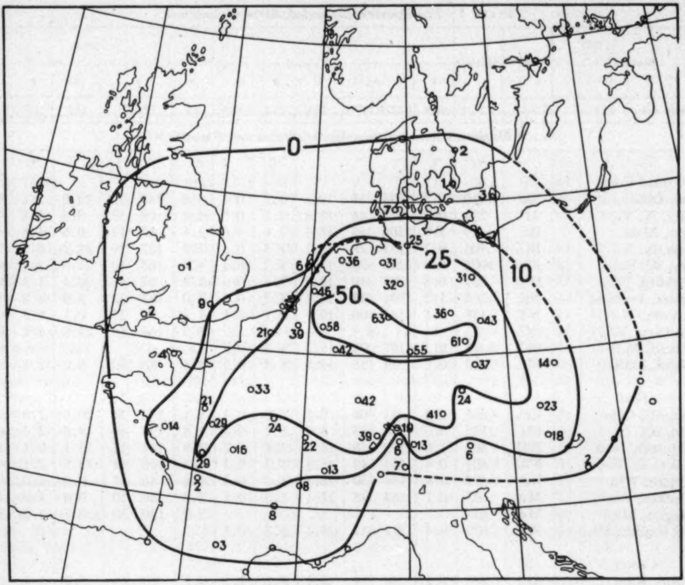

FIG. 2 – The heat waves in western Europe in 1947

the zero line, whereas for lower values of $\mathbf{a}_r$ it passes this line and the concordance between the observed data and the harmonics decreases rapidly. For $\mathbf{a}_r > 1$ the concordance may be considered to be sufficient. Yet, we have taken $\mathbf{a}_r = 0.8$ as the lowest reduced amplitude acceptable.

The curves reveal close connections with the sunspots, but in great variety. Compare Figure 1a with the others for 1947, and Figure 1g with the others of 1953.

The data—The sunspot maximum year 1947 showed a remarkably well-developed series of eight consecutive regular 27-day periods between April 14 and November 7 (rotation numbers 1559–1566 after Bartels's counting). These periods were followed by considerable heat waves over central Europe [*Visser*, 1949ab]. A rough survey over 45 years, 1910–1954, showed repeated occurrences of such cases [*Visser*, 1954]. Moreover, there were indications that the same effects, though on a smaller scale, were encountered in the United States [*Visser*, 1954]. These preliminary investigations induced a more exact study of the effects found.

The year 1953 was chosen because of the weak sunspot activity (one year before the minimum). This year contained a series of four regular sunspot waves, January 27–May 11 (Bartels's numbers 1637–1640). Notwithstanding the low solar activity, a periodic influence on the temperature, similar to that in 1947, (see Fig. 1) is evident.

Figure 2 shows the extent and intensity of the

$\mathbf{a}$ = harmonic amplitude; θ = phase angle; D = maximum day; σ = standard deviation; $\mathbf{a}_r$ = reduced amplitude.

1947 series at 69 stations in western Europe [*Visser*, 1954]. The intensity has been characterized for each wave at each station by a scale of 1 to 6, 1 for amplitudes generally more than 3°C below the average value, 6 for amplitudes generally more than 3°C above. The sum of these values is considered to represent the total intensity of the phenomenon. Maximal intensity (sums above 50) occurs in central Europe (Maastricht, 58; Marburg, 63; Bad Kissingen, 55; Fichtelberg, 61).

Figure 3 presents the stations in the United States and Canada which have been studied. The reduced amplitudes have been marked by open circles, for all values of $\mathbf{a}_r$ equaling or exceeding 0.8 being indicated by filling in half of these circles, the left half representing 1947, the right

1953. Table 1 provides a key to the stations and other pertinent information.

Certain characteristic differences have been noted. In the eastern states 1953 is the more outstanding (to Milwaukee, Mw), in the central states 1947. Along the continental divide is an area in which 1953 stands out. In the western states the connection is well developed in both years, with the exception of the coastal stations which do not show clear connections in either year.

We have divided the United States into six areas (see Table 1) in the East, East Coast, East, and Center; in the West, transition zone East-West, West, and West Coast. It was not always possible to fix the limits between these areas exactly, so we have referred the periodic characteristics to the geographical positions. Thus, for example, Akron, Ohio, and Elkins, West Virginia, are shown in the East Coast stations, though they are over 200 mi inland.

Regarding the 52° circle of geomagnetic latitude (Fig. 3), see *The ionosphere* below.

More particulars are to be found in Figure 4 for the northwestern states and Canada for 1947 and 1953, respectively. On these maps the intensity has been expressed in the reduced amplitude; the numbers inscribed at each station indicate the average maximum day. Figures 2 (Europe) and 4 (western United States and Canada) show similar features, a central area with high intensity decreasing toward the coasts and inland.

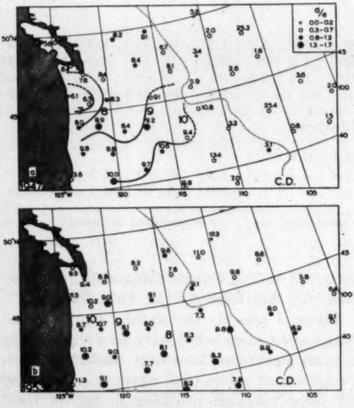

FIG. 4 – The 27-day period in western United States and Canada, 1947 and 1953

In 1947 a propagation in the western area from northwest to southeast is obvious, the maximum taking from Day 7 to Day 10 to cross the country. The data exhibit an abrupt change of phase east of the continental divide. It is impossible simply to extend the isochrons to the eastern area. One is inclined to consider the continental divide as a barrier to the propagation. Two stations, however, situated at the west side (Big Piney, Wyoming, and Hayden, Colorado), behave in a manner similar to those in the east, perhaps because of some orographical influence.

In 1953 west of the continental divide the maxima arrive on the same days as in 1947, but the propagation is from east to west (Days 8 to 10). Moreover the continental divide does not act as a barrier; on both sides we note that the maximum days are the same.

The reduced amplitude—The systematic differences in $\mathbf{a}_r$ between the two years 1947 and 1953 are demonstrated in Figures 5 and 6. The $\mathbf{a}_r$ values for 1947 are the abscissae, those for 1953, the ordinates. The limiting value $\mathbf{a}_r = 0.8$ is indicated by vertical and horizontal lines. The six areas adopted have been marked by different symbols.

At a glance we see the opposite behavior of the two years in the eastern areas (Fig. 5), whereas in the West (Fig. 6) the two years behave in the same way. In particular we do not find stations in the upper right-hand square of Figure 5 and only one (Spokane, Washington) in the lower right-hand part of Figure 6.

The East and East Coast stations show a well-developed periodicity in 1953 in contrast to 1947; the central stations, all of them around about 95° W, on the other hand, had a strong periodicity in 1947, a weak one in 1953.

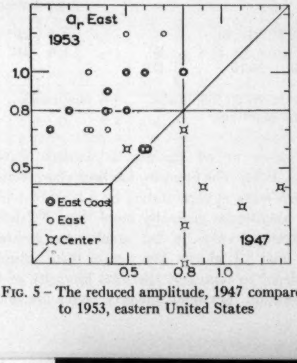

FIG. 5 – The reduced amplitude, 1947 compared to 1953, eastern United States

Figure 6 shows the period to be poorly developed in both years at the three West Coast stations, positive correlations in both years at the West stations, all of them situated on the west side of the continental divide. In the area of the East-West stations (the transition zone between the continental divide and the Central stations) the periodicity as a rule is poorly developed in both years.

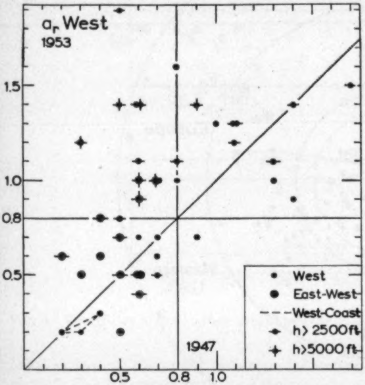

FIG. 6 – The reduced amplitude 1947 compared to 1953, western United States

It is possible to study the influence of the height above sea level h in the western areas. The stations with altitudes ranging from 2500 ft up to 5000 ft generally behave in a manner similar to lower ones. Without exception stations above 5000 ft experienced a stronger periodicity in 1953 than in 1947.

The results—The complete results of the investigation are represented in the clock diagrams, Figure 7 for 1947 and Figure 8 for 1953. The 27 days of the period have been arranged as the figures of the clock's face and the stations have been plotted by means of the maximum day and the reduced amplitude as polar coordinates. Here again the limit of $a_r = 0.8$ has been indicated. In these figures some other phenomena have been introduced, which will be discussed below.

As a consequence of the method used we find the sunspot maximum at Day 13.5; its reduced amplitude lies far outside the limits of the figures.

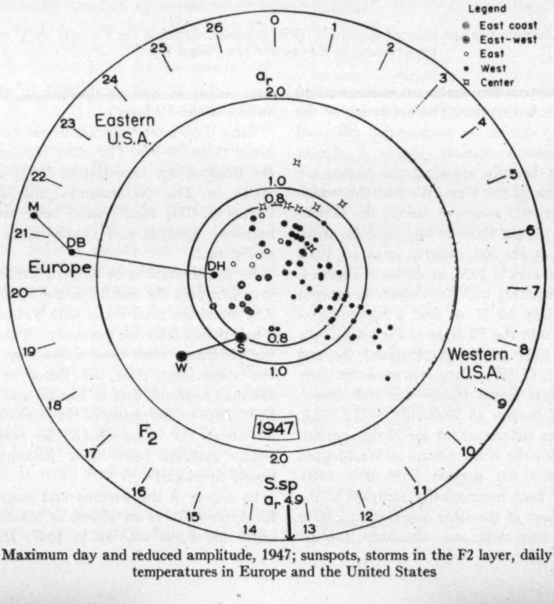

FIG. 7 – Maximum day and reduced amplitude, 1947; sunspots, storms in the F2 layer, daily maximum temperatures in Europe and the United States

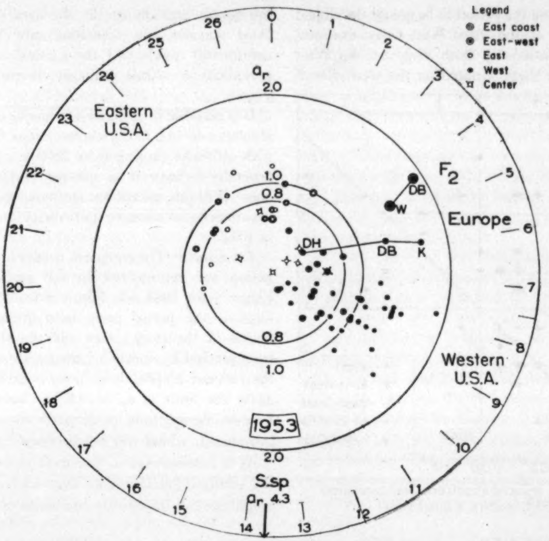

Fig. 8 – Maximum day and reduced amplitude, 1953; sunspots, storms in the F2 layer, daily maximum temperatures in Europe and the United States

We see the western stations accumulating around about Day 9 in both years. The scattering of the points is wholly due to the propagation discussed above. The eastern stations display a greater scattering, but broadly speaking the phases are opposite to those of the West. We find the transition stations in 1947 scattered among the eastern ones; in 1953 among those of the western areas. They behave as do the eastern areas in 1947, like the western area in 1953, as shown in Figure 4.

In Figure 7 starting with the maximum sunspot Day 13.5, at Day 16–17 we find a maximum of magnetic storms in the F2 layer of the ionosphere. The F2 data refer to Slough, England (S) and Washington, D. C. (W). They represent the daily number of storm hours [*Radio Research Board*, 1947; *National Bureau of Standards*, 1947; 1953]. They have been calculated for six 27-day periods only, 1561–1566, the observations in Washington being incomplete for periods 1559 and 1560. The data have been harmonically analysed in the same way as those of the other observations. Both stations agree very well, and, obviously, the 27-day period is well established in the magnetic storms of the F2 layer.

Some days later temperature maxima in Europe occur (Day 20–21). The three stations plotted in the diagram are Den Helder (DH) and De Bilt (DB) in The Netherlands, and Marburg in Germany. The results have been arrived at by harmonic analysis and closely agree with those of Figure 2.

As to the stations of western United States we may interpret the results of the figure as follows. The minimum must occur with a time interval of a half period after the maximum. This means that the minimum must present itself at Day 22–23, two days later than the European maximum. We may conclude that in Europe and the western United States the phases of the period are opposite. At about the same epoch the eastern United States stations have their maximum, though poorly developed.

In Figure 8 the western and eastern areas of the United States are shown to behave in 1953 in quite the same way as in 1947. However, the

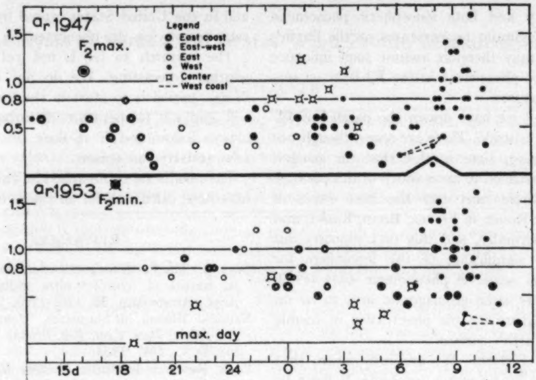

Fig. 9 – The 27-day period in the United States and Canada, maximum day and reduced amplitude, 1947 and 1953.

behavior in the F2 layer and in Europe are contrary to 1947. The F2 storms experience their maximum value at Day 4 and have, therefore, their minimum at Day 18. The two F2 points in the diagram represent the daily amount of storm hours in Washington (as in 1947) and the I-index in De Bilt (see also Fig. 1h). Again, there is a good agreement, and the period is in the ionosphere well developed.

In 1953 as in 1947 European temperature maxima follow the F2-storm maxima (Den Helder and De Bilt, as before, and Kassel-Harleshausen (K) in Germany) at Day 5. Their minimum occurs at Day 19.

Figure 9, finally, represents the features in two rectangular diagrams, the maximum days as abscissae, the reduced amplitudes as ordinates. Only the average F2 figures have been plotted in these diagrams. This figure presents some of the features more clearly than do the clock diagrams. For example, the weak development and the broad scattering of the central stations is well established. The moving of the East-West maxima from Day 26–7 in 1947 to Day 5–12 in 1953 is clear. We point to a similar moving of the East-Coast maxima from Day 16–20 in 1947 to Day 21–2 in 1953. However, especially in 1947, the intensity is small and probably statistically insignificant.

The ionosphere—In the previous section we have found indications of a possible link between the

Maximum day	(26.9)	(24.9)

solar activity and both ionospheric phenomena and daily maximum temperatures on the Earth's surface. We may therefore assume some influence of the electric phenomena in the F2 layer on sea-level temperatures.

In Figure 3 we have drawn the parallel of 52° geomagnetic latitude. There are some, though not very convincing, signs in this that the sunspot influence is confined to areas south of this parallel. This same circle runs over the heat waves of Europe, over Rouen in France, Bonn, Kassel, and Dessau in Germany, and this fact supports our view of the significance of the ionosphere for meteorological sea-level phenomena. *Clay* [1932] has found this same geomagnetic area to be an important feature for the penetration of cosmic rays to the Earth's surface.

Concluding remarks—We are fully aware that this survey is by no means complete. It must be extended over a greater part of North America and elsewhere, but the results are so characteristic that it seems worth while to investigate these matters thoroughly.

We do not speak of the explanation. We do not know enough of the circumstances either at the solar surface, or in the ionosphere, or even in the troposphere, to enable us to discuss the theoretical fundamentals of the phenomena disclosed in this paper.

Since the maximum temperature depends upon the general atmospheric circulation an intensive study of the synoptic situation should follow. On this side of the problem *Rodewald* [1955–1956] has made important contributions. It is now a well established fact that seasonal effects are active, but the data available are still insufficient to deduce them. I should like to point to the possibility of some blocking action in western Europe and in the United States caused by the effects of solar activity on the phenomena in the F2 region.

The research so far is not yet applicable to weather forecasting. We do not know when a 27-day period is to start in the Sun nor when it will end. A temperature disturbance does not always follow and if it does, it depends upon solar activity and season.

The results are summarized in Table 2 (averages have been calculated for all values of $\mathbf{a}_r > 0.8$).

An Analysis of Some Over-Water Wind Profile Measurements

N. K. Wagner

Abstract—For several days during the spring of 1955, wind-speed profiles were measured from an oil drilling platform in the Gulf of Mexico. Various standard parameters such as the friction velocity, roughness parameter, surface stress, and resistance coefficient are computed from these profiles. Functional relationships are derived between the various computed parameters and the wind speed at ten meters. A re-analysis of data obtained by Wüst in 1919 shows that it is in very good agreement with the present data.

An attempt is made to relate the roughness parameter with the root-mean-square of the water-level fluctuations, and though some indication of a dependence can be inferred, there is too much scatter of the plotted points to arrive at a unique functional relationship.

Introduction—During the period April 19 to May 2, 1955 meteorological and oceanographic measurements and observations were taken in conjunction with field measurements of the over-water propagation of microwave frequency electromagnetic waves at low elevation angles. Although a wide variety of interesting data were obtained [*Wagner* and *Gerhardt*, 1957] only the wind-profile analysis will be discussed in this paper.

The site of the meteorological observations was an oil drilling platform in the Eugene Island area of the Gulf of Mexico, off the coast near Morgan City, Louisiana. The platform is about 30 mi from the mainland and stands in about 35 ft of water. The top of the platform is 32 ft above mean low water.

Instrumentation and observations—A light triangular aluminum tower mounted on the southeast corner of the platform served as a support for three 3-cup dc anemometers at 2.8, 7.2, and 13.0 meters above mean low water. Three-foot booms were employed in removing the anemometers from the immediate vicinity of the tower and platform. With the platform oriented exactly north-south, this installation permitted the measurement of undisturbed air flow for wind directions from approximately north clockwise through southwest. The anemometer output was recorded on Esterline-Angus strip-chart recorders having a full scale calibration of 0 to 50 mi/hr.

Because the meteorological observations were coordinated quite closely with the radio data runs, the wind data consisted of five and ten minute samples of the wind speed. Only the ten minute wind-speed samples are used in this analysis. In comparing these ten-minute mean wind profiles with one another, quite large variations were occasionally found in the measured wind speed between runs taken only a few minutes apart. For this reason it was decided that the ten-minute averaging time was too short to obtain a representative mean wind profile. Instead, each day was arbitrarily divided into three time periods, and all of the ten-minute profiles falling within each of these time periods were averaged. Thus, each day consists of: (1) a mean morning profile consisting of all ten-minute profiles taken between about 06h 00m and 10h 00m; (2) a mean midday profile consisting of all ten-minute profiles taken between 10h 00m and 14h 00m, and, (3) a mean afternoon profile which consists of all ten-minute runs taken between 14h 00m and about 20h 00m (all CST). Each time period contains about 50 minutes (five samples) of data. All of the ten-minute runs for each day were also averaged in order to obtain a mean daily wind profile.

Plotting the profiles—When wind profile observations are made over-land, the anemometer height is designated as the height of the instrument above the surface of the ground. When dealing with mean profiles over water it is often quite difficult to say exactly how high the anemometers are above the water surface. The anemometers during these experiments were at a fixed height above the mean low-water level, thus there was a variable distance between the actual water surface and the anemometers not only because of variable wind wave and swell heights, but also because of tidal fluctuations.

In an effort to minimize this difficulty, the mean water level during each time period and each day was computed from the theoretical tide data for Ship Shoal Lighthouse, which is located about 20 mi to the east of the observation platform. These computed values were used for the mean height of the water surface for each time period and daily mean wind speed profile, respectively. Using this height correction factor, the mean profiles are

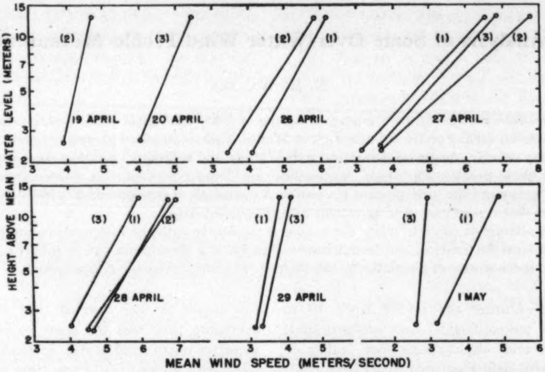

FIG. 1 – Mean wind-speed profiles for the time periods: (1) 06h 00m to 10h 00m, (2) 10h 00m to 14h 00m, and (3) 14h 00m to 20h 00m (all CST)

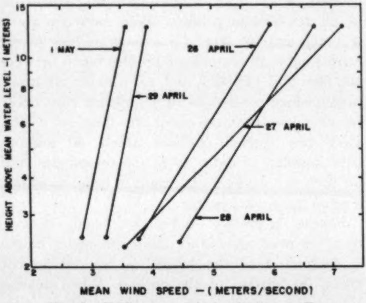

FIG. 2 – Daily mean wind velocity profiles

plotted with a logarithmic height scale in Figures 1 and 2.

On the last day of data collection, the anemometer at the middle level (7.2 m) was found to be indicating a wind speed which was much too low. On some occasions the cups would stop completely, while the anemometers at the other two levels remained in motion. An inspection of the instrument showed that friction tape, which was used to hold the electrical leads in place, had become lose and was becoming lodged between the stationary portion of the anemometer and the rotating weather shield.

Examination of all data from the middle anemometer made it appear likely that this condition had been present, but unnoticed, for some time. Thus, in Figures 1 and 2 and the following analysis the middle anemometer data have been omitted and a strict logarithmic (neutral stability) wind profile is assumed. On the basis of computed Richardson numbers this appears to be quite a valid assumption.

Computations from the profiles—In order to compare these data with the results obtained by others, various standard parameters may be computed from the mean wind profiles. Having assumed a logarithmic wind profile defined by the upper and lower mean wind speeds, the roughness parameter z_0 and the friction velocity U_* are found by determining the zero wind intercept and the slope of the profile, respectively. From the resulting values of the friction velocity, values for the surface stress τ are computed from the formula

$$\tau = U_*^2 \rho \tag{1}$$

where ρ is the air density.

Values for the resistance coefficient are also computed. The resistance coefficient γ^2 is a dimensionless parameter defined by *Taylor* [1916] as

$$\gamma^2 = \frac{\tau}{\rho U^2} = \frac{U_*^2}{U^2} \tag{2}$$

In order to be consistent with previous determinations of this parameter, the interpolated ten-meter mean wind speed is used for U.

The Richardson number, defined by

$$Ri = \frac{(g/T)((\partial T/\partial z) + \Gamma)}{(\partial U/\partial z)^2} \tag{3}$$

is computed for each time period when data permitted. In (3) T is the absolute temperature, g is the acceleration of gravity, and Γ is the adiabatic lapse rate. The vertical gradients of temperature are computed from the psychrograph sounding levels of zero and 25 ft below the top of the platform, and the wind gradient from the lower and upper mean wind speeds.

Discussion of the data—The relationship between the shape of the wind profile and the Richardson number has been discussed by *Deacon* [1949]. For our assumption of a semi-logarithmic relationship between wind speed and height to be considered valid it must be shown that the atmosphere was adiabatically stratified during periods of data collection. ***Neumann*** [1956] has stated that normally the atmosphere is in neutral equilibrium over large bodies of water. Computations of the Richardson number from (3) give additional verification to Neumann's statement. These values are given in Table 1. It may be seen from these data that the computed Richardson numbers show an essentially adiabatically stratified atmosphere.

A very wide range of values was found for the roughness parameter. The smallest value of 5×10^{-4} centimeters occurred during the third time period on May 1 and the largest value of 51 centimeters during the second time period on April 27. An examination of the literature gives little support for the larger magnitudes obtained in this analysis. Some of the better known values for the roughness parameter as obtained over a water surface are summarized in Table 2.

TABLE 1 – *Computed values for the Richardson number*

Date	Time period	Richardson number

TABLE 2 – *The roughness parameter over water as determined by various investigators*

Investigator	z_0	Dependence on wind speed
	cm	
Rossby and *Montgomery* [1936]	0.6	6.5 m/s at 6 m
Model [1942]	0.07	Independent of wind speed
Deacon [1953]	0.02 to 0.04	7.5 m/s at 15 m
Hay [1955a]	0.02 to 0.25	Linear dependence on 2 m wind speed from 5 to 9 m/s
Present analysis	0.0005 to 51.0	An approximately semi-logarithmic dependence on 10 m wind speed from 3 to 7 m/s

Plots of the interpolated wind velocity at ten meters against the friction velocity and the roughness parameter are shown in Figures 3 and 4 respectively. The general trend of these two graphs is intuitively satisfying; that is, as the ten-meter wind speed increases, the friction velocity and the roughness parameter increase. This implies that the configuration of the water surface is largely dependent on the wind speed and that with increasing wind velocities there occurs an increase in the roughness characteristics of the water surface and an increase in the stress at the air-water boundary.

The solid lines on Figures 3 and 4 represent the straight lines of best fit (by eye) for the plotted data. The equations for these lines (in cgs units) are, from Figure 3

$$\ln U_{10} = 0.369 \ln U_* + 4.868 \tag{4}$$

and from Figure 4

$$\ln z_0 = 0.023 \ U_{10} - 11.086 \tag{5}$$

The logarithmic wind profile is normally given by the formula

$$U = \frac{U_*}{k} \ln \frac{z}{z_0} \tag{6}$$

where k is von Karman's constant (assumed equal to 0.400). If we let U represent the wind speed at ten meters then (6) may be written

$$U_{10} = \frac{U_*}{k} (3 \ln 10 - \ln z_0) \tag{7}$$

Eq. (7) and all of the ensuing development will be in cgs units.

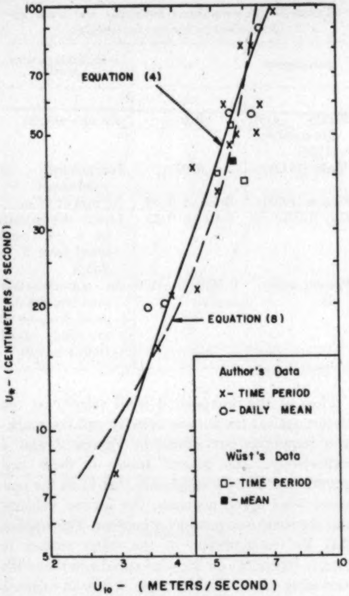

FIG. 3 – The friction velocity plotted against the ten-meter wind speed

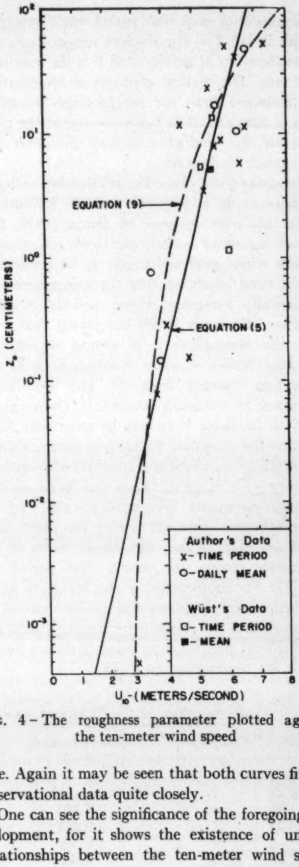

FIG. 4 – The roughness parameter plotted against the ten-meter wind speed

Theoretically, if (4) and (5) accurately represent the data, then by substituting (4) into (7) one should obtain (5). Likewise, by substituting (5) into (7) one should obtain (4). Substitution for ln z_0 from (5) into (7) and solving for U_{10} gives

$$U_{10} = \frac{17.994\ U_*}{0.400 + 0.023\ U_*} \tag{8}$$

Eq. (8) is plotted as a dashed line in Figure 3. Both the estimated and semi-empirically derived curves are quite close together and each curve adequately describes the data.

The same procedure can be followed to obtain a second equation relating the roughness parameter and the ten-meter wind speed. Substitution for U_* from (4) into (7) and a rearrangement of terms gives

$$\ln U_{10} = 0.585\ \{12.276 - \ln (6.908 - \ln z_0)\} \tag{9}$$

Eq. (9) has been plotted on Figure 4 as a dashed line. Again it may be seen that both curves fit the observational data quite closely.

One can see the significance of the foregoing development, for it shows the existence of unique relationships between the ten-meter wind speed and the friction velocity, and the ten-meter wind speed and the roughness parameter. By measuring only the ten-meter wind speed (U_{10}) the friction velocity and roughness parameter can be determined either by a simple computation involving (4), (5), (8), or (9) or by employing Figures 3 and 4.

Figure 5 shows the friction velocity plotted against the roughness parameter. Elimination of U_{10} by combining (5) and (4) yields

$$\ln U_* = 2.710 \ln (\ln z_0 + 11.086) - 2.967 \tag{10}$$

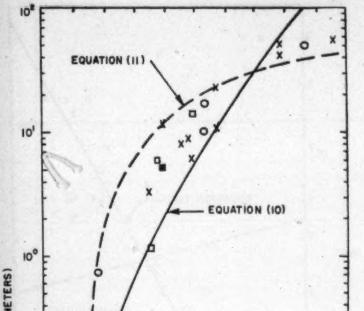

FIG. 5 – The roughness parameter plotted against the friction velocity

This equation is plotted as a solid curve in Figure 5. A second relationship may be derived between U_* and z_0 by combining (8) and (9). This gives

$$\ln \frac{U_*}{0.400 + 0.023\, U_*}$$

$$= 0.585\,\{12.276 - \ln(6.908 - \ln z_0)\} - 2.890 = f(z_0)$$

and solving for U_*

$$U_* = \frac{0.400 \exp[f(z_0)]}{1 - 0.023 \exp[f(z_0)]} \tag{11}$$

Eq. (11) is plotted as a dashed curve in Figure 5. As one would expect, (10) and (11) both accurately describe the data given in Figure 5.

In an attempt to find independent data which would help to verify the relationships shown in Figures 3, 4, and 5 the author re-analyzed Wüst's data (as given in *Rossby* and *Montgomery* [1936]). In order to be consistent in the method of analysis, Wüst's wind data for one and six meters above the water surface were reduced to time period mean wind speed profiles as shown in Table 3.

Also indicated in Table 3 are mean values for the various parameters determined by averaging the values for $\bar{U}_6$ and $\bar{U}_1$ for time periods 1, 2, and 3. Values for the ten-meter wind speed were found by assuming adiabatic conditions and extending the profile up to the ten-meter level.

The resulting values for the roughness parameter, friction velocity and ten-meter wind speed can then be plotted on Figures 3, 4, and 5. Examination of these figures shows that Wüst's data agrees well with the author's data.

Figure 6 is a replot of the data given in Figure 3. The surface stress is proportional to the square of the friction velocity as shown by (1), therefore in Figure 6 the stress is plotted against the square of the wind velocity at ten meters. The equation for the straight line of best fit may be determined as follows: Squaring both sides of (4), assuming an air density value of 1.25×10^{-3} gm/cm³, and employing the relationship given by (1) yields

$$\ln U_{10}^2 = 0.369 \ln \tau + 12.227 \tag{12}$$

The dashed curve in Figure 6 represents stress data obtained by *Moore* and *Laird* [1957] in a wind tunnel using a stationary mechanical wave boundary. There is an apparent divergence of the two sets of data in the high wind speed region, however, because of the differences between the two systems employed for analysis the agreement is considered to be quite good.

Figure 7 shows the variation of the resistance coefficient with the square of the wind velocity at ten meters. The equation for the straight line of best fit is

$$\ln U_{10}^2 = 0.544 \ln \gamma^2 + 12.766 \tag{13}$$

TABLE 3 – *A re-analysis of Wüst's over-water wind data*

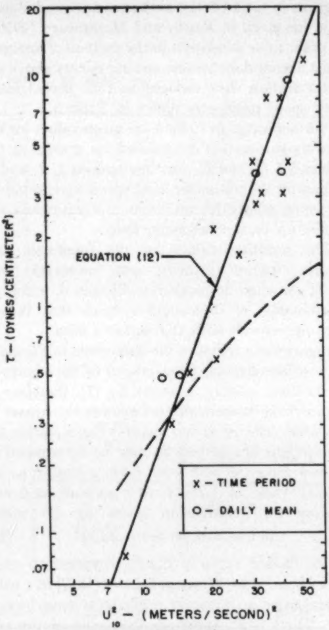

FIG. 6 – The surface stress plotted against the square of the ten-meter wind speed

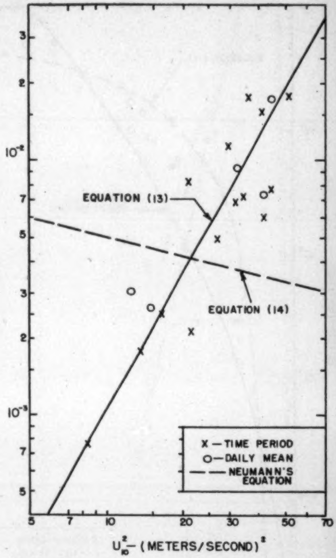

FIG. 7 – The resistance coefficient plotted against the square of the ten-meter wind speed

An interesting feature of Figure 7 (or (13)) is that it shows the resistance coefficient increasing almost twice as fast as the square of the ten-meter wind speed. This is very much in disagreement with the findings of other researchers (see *Hay* [1955b], *Neumann* [1956], or *Dietrich* and *Kalle* [1957] for a summary of the better known values). In particular, Neumann has derived the empirical relationship

$$\gamma^2 = 9 \times 10^{-3} \left(\frac{100 \text{ cm/sec}}{U} \right)^{1/2} \tag{14}$$

between the wind speed and the resistance coefficient based on the results of sea-surface slope observations.

Eq. (14) is plotted as a dashed line in Figure 7. The discrepancy between (13) and (14) is quite obvious. Unfortunately, wind profile corrections of the type suggested by *Neumann* [1951] will not cause any better agreement between these two formulas, since the net result of the corrections is to give an increase in the value of the computed resistance coefficient.

Even though the individual points in Figures 3–7 show some scatter, there is no indication of any discontinuity in the general trend of the points. This is in disagreement with *Munk's* [1947] hypothesis that a wind velocity of 7 m/s at 15 m was accompanied by a discontinuity in the resistance coefficient and initiated the occurrence of whitecaps. Neither of these discontinuities was evident in the present analysis. This is not the first time the critical wind-speed concept has been questioned [*Neumann*, 1956]. Even *Munk* [1957] has conceded that the existence of a critical wind speed is somewhat doubtful.

An attempt was made to relate the roughness parameter to the water-level fluctuations as measured by a step wave gage. Because the roughness parameter was found to increase with the ten-meter wind speed and because wind waves also increase in amplitude with increasing wind speeds, one would intuitively expect a relationship be-

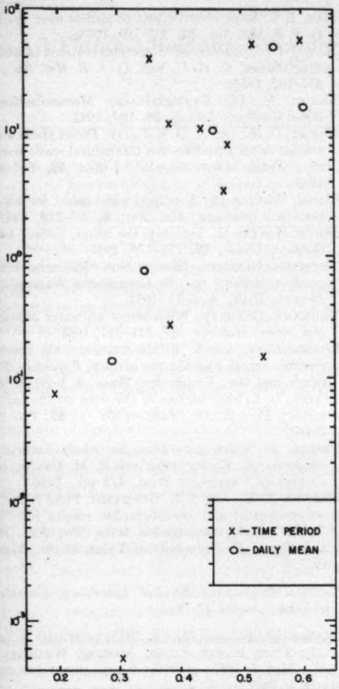

FIG. 8 – The roughness parameter plotted against the water-level fluctuation root-mean-square value

tween these two parameters. A plot of these data is shown in Figure 8. Although there is some indication of a relationship, the plotted points have considerable scatter. This scatter is thought to be caused by the inability of the wave gage to separate the wind effects on the water surface from the swell. For example, on April 19 the roughness parameter was found to be 0.15 cm while the root-mean-square of the water level fluctuations was computed to be 0.53 foot. Visual observations of the water surface during this time period show that the water-surface fluctuations were almost entirely caused by a smooth sea swell from the southeast with only occasional wind ripples. The problem of relating the roughness parameter to water level fluctuations, whether it be wind waves, ripples, or some other water surface disturbance, offers interesting possibilities for future research.

Data reliability—The anemometers used for these observations were calibrated in a wind tunnel less than two months before the start of the measurement program. After these calibration tests the anemometers were boxed and stored until mounted on the platform in the Gulf of Mexico. It is felt that sufficient calibration information was available to make errors from this source insignificant.

Many problems arose during the reduction of the data, only a few of which were resolved. The high starting torque of the anemometers made any mean wind speed below about five miles per hour (2.2 m/s) of doubtful reliability, therefore all profiles containing speeds below this figure were eliminated from the analysis. This does not mean that these lower wind speeds are unimportant as far as transfer processes at the air-water boundary are concerned. Instead we are simply stating that it was impossible to determine these low wind speeds with the accuracy necessary to arrive at valid conclusions, and for this reason they were omitted. Another problem was that of having only two usable anemometer levels. More levels would have been desirable in order to describe more accurately the over-water wind profile. In particular it would have been desirable to have at least one anemometer located closer to the water surface.

Even though a fixed oil drilling platform may have certain advantages over a raft as an observing station, certainly one of its disadvantages is the inability to keep the anemometers at a fixed height above the water surface. On a raft this problem is not completely solved, what with wind waves and swell to contend with, but the fixed platform presents the added complexity of tidal fluctuations. There may be some question as to the validity of employing a mean anemometer height correction, especially during periods of rapid tidal fluctuations, but it gives at least a first approximation as to the mean height of the anemometers above the water surface.

The final problem to be discussed is that of current. If the water is moving under the influence of wind, tide, or swell, then it seems probable that in order to make a true application of the wind profile equation, the wind speed should be measured relative to the speed of the surface water current. A somewhat analogous statement was made by *Ursell* [1956] when he said, "It may be necessary to measure wind velocities relative to the speed of travel of the roughnesses." Unfortunately, a current meter was not included in the instrumentation for this project. Also, since no investigator seems to be definite as to what these roughnesses represent over a water surface, it is indeed difficult to measure their speed of travel.

Conclusions—Open-air measurements of wind-speed profiles over water is indeed a complicated and intricate task. In general, the data and analyses reported in this paper tend to conflict with previous experimental findings. However, in most instances, some supporting data can be found. The only firm conclusion that can be reached is that which describes the apparent state of knowledge concerning the energy balance and transfer processes between the Earth's atmosphere and oceans; that is, we have much to learn. To insure at least partial success of future missions, the combined talents of the meteorologist and oceanographer are required, for only through cooperative efforts and well planned experiments can some of the present day problems be resolved.

A Portable Raindrop Recorder for Semi-Continuous Determination of Size Distributions*

A. T. SPENCER AND D. C. BLANCHARD

Abstract—The recorder was designed to obtain adequate drop samples, in the size range of 50 to 2000 microns diameter, at about two-minute intervals for a period in excess of 24 hrs. Successful field use of several instruments in a cloud physics study is indicated and they are described in some detail.

Introduction—During the planning stages of Project Shower [*Blanchard* and *Spencer*, 1957; *Squires*, 1955] the need arose to obtain continuous records of the fluctuation of the raindrop size in the orographic clouds on the Island of Hawaii. This need grew out of earlier ideas [*Blanchard*, 1953; *Woodcock*, 1952] of the importance of detailed knowledge of raindrop size distributions as an aid to understanding 'warm' rain formation. The purpose of this paper is to describe the instrument which was designed to answer our questions about drop size and number differences as a function of time and substance within orographic clouds.

A variety of automatic sampling devices have been developed and used [*Bowen* and *Davidson*, 1951; *Cooper*, 1951; *Fugiwara*, 1954; *Katz*, 1952; *Maulard*, 1951], but none of them, with the possible exception of the raindrop spectrograph of Bowen and Davidson [1951], appeared to have sufficient accuracy, compactness, and portability for the present work. Thus it seemed advisable to design and build a small device that would incorporate the above features.

Earlier work in Hawaii had shown that the rain from orographic clouds was not uniform but that great fluctuation in intensity and rain drop size occurred. Individual showers, imbedded within the orographic cloud system, appeared to move up the mountain slopes while the median raindrop size progressively decreased with increasing elevation [*Blanchard*, 1953].

Since we needed to determine the rate of change of the drop distribution as a function of time and distance along the mountain slope, it was necessary to construct a number of portable instruments that could be used to obtain measurements simultaneously at several elevations. As no source of power was available on the mountain, the instruments had to be self-contained and portable. It was decided to build instruments that would expose a section of dye treated paper tape at intervals of about two minutes. The splash pattern on the tape could then be related to raindrop size by appropriate calibration methods.

Although the instrument to be described in this paper was designed specifically for use in Hawaiian orographic rains where the raindrops seldom exceed two millimeters diameter, there is no reason why minor changes in the design could not make it adaptable for use in heavier rains. The present design should also be adequate for the light steady rains that are commonly associated with the passage of a warm front.

Instrument description—The dimensions of the drop recorder shown in Figures 1-3, are 6 × 8 × 11 inches. It weighs twelve pounds, excluding the weight of the power source. The operation of the recorder is as follows: at two minute intervals a sliding shutter opens and exposes a section of paper tape to the rain. The shutter remains open for approximately 2.7 sec. During the nearly two-minute period that the shutter is closed, the paper tape is dried by a heating coil and the 'take up' spool advances an unexposed section of paper tape into position for the next exposure.

The tape is standard, 3½ inches wide, adding machine paper which was impregnated with dry methylene blue chloride powder. Sufficient dye was polished into the paper, as illustrated on Figure 4, to produce a uniform pale blue color.

The opening in the cover, through which the rain falls (see Fig. 2) has an area of only 33 cm². However, past studies of typical trade-wind shower rains [*Blanchard*, 1953] show that a two or three-second exposure allows from 60 to 200 drops to be collected on a 33 cm² surface. In most cases this is a sufficient number to establish the drop size distribution with useful accuracy.

The two small, 12-v dc motors and the 16-watt

---

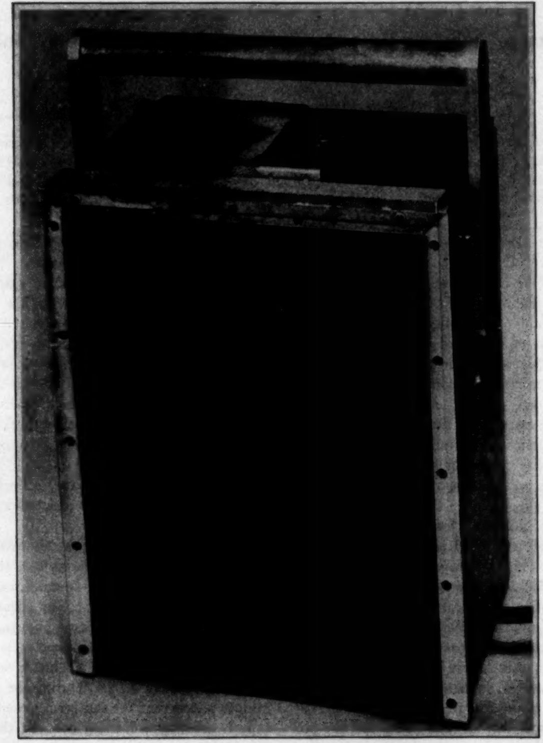

FIG. 1 – Front view of recorder showing ventilation louvers in access door and sliding door in closed position

heater coil of the recorder, are powered by a 12-v dc automobile battery. This battery will operate the recorder for 24 hrs without recharging. One of the two motors runs continuously as a timing motor. The second motor transports the paper and opens the sliding hatch to expose the tape. The heating coil is turned off, shortly before the tape is exposed, to prolong the life of the battery between charging periods.

The top surface of the case, as well as the sliding shutter, are made of Formica, a laminated plastic material of low heat conductivity. This allows the inside surface of the cover and hatch to attain a sufficiently high temperature so that condensation of the water vapor, which is evaporated from the tape does not take place. There is sufficient space between the sliding hatch or shutter, and the top surface for the vapor from the drying tape to escape to the outside air. Circulation is facilitated by the ventilation louvres revealed on Figure 1.

The fine wire mesh, which stands approximately ¼ inch above the top surface, prevents raindrops from striking the outside rigid surfaces and splashing onto the tape when the shutter is open. The splash of raindrops striking the wire mesh or the paper tape was negligible for drops of less than two

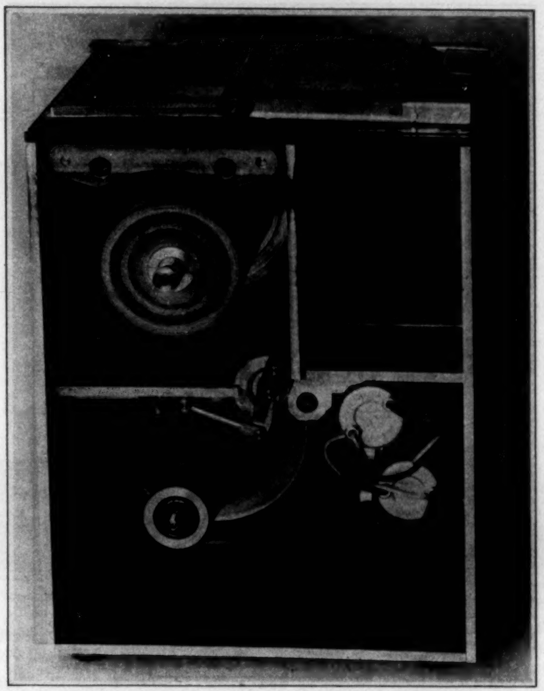

FIG. 2 – Front view of raindrop recorder with access door removed, and showing sliding door in open position

millimeters diameter. For drops larger than two millimeters the splashed drops were generally smaller than 0.2 mm.

The relatively constant rate of rotation of the small dc motors, produces a usefully constant relationship between the length of paper tape exposed and time. Thus the time of exposure of any given rain record can be extrapolated or interpolated from a few time marks manually placed on the tape during a 24-hr period.

Discussion—The drop recorders obtained excellent records in the Hawaiian orographic rains when the rain did not exceed intensities of about 25 mm hr^{-1} (see Fig. 5). The exposure time of 2.7 sec was satisfactory even when sampling the very light rains in the range of 0.1 to 1 mm hr^{-1}. Although the drops in these light rains are generally less than 500 microns diameter and thus have a low settling speed, they are present in great numbers. Consequently, the number of drops striking the recorder tape per unit time will often equal, if not exceed, that when the rain intensity is higher. This will hold true only when the sampling is done in a region where the small drops are not subject to evaporation in their fall from source to ground. At intensities greater than about 25 mm hr^{-1} the increased size of the imprint pattern of the drops resulted in overlapping and in the production of small drops by splashing.

The calibration of the recorder tape was done by letting various sized drops strike the tape at terminal velocity. Drops as small as 50 microns

diameter leave imprints on the dyed tape that are sharp and clear. With such small drops a low-power microscope is necessary to measure the imprint. The imprint diameter is a function of raindrop size and is from 1.5 times the drop diameter at 50 microns to about ten times the drop diameter at two millimeters. In the range commonly associated with raindrops ($>$ 200 micron diameter) the original drop size may be determined from the imprint diameter by using a properly calibrated scale. With the aid of graphs, the drop distribution thus obtained may be converted into rain intensity or the volume distribution of raindrops.

An instrument of the type here described is useful in many cloud physics and radar weather studies. Further discussion of the use of the re-

An Empirical Method for Estimating Wind Profiles over Open, Level Ground

DAVID N. KEAST AND FRANCIS M. WIENER

Abstract—An analysis of several hundred measured mean wind and corresponding mean temperature profiles has led to an empirical method for estimating wind profiles up to a height of approximately 30 ft above ground cover over open, level ground. This method makes use of two simple measurements: (1) a measurement of the vertical temperature difference between two heights in the range between one foot and 15 ft above ground cover, and (2) a measurement of the horizontal wind speed at a height of about 30 ft or less above ground cover. The mean wind profile is then estimated by means of a contour chart. The limitations and errors involved in the use of this prediction procedure are discussed, and several examples comparing predicted profiles with their measured counterparts are presented. The procedure is proposed for the many practical situations where one wishes to obtain approximate wind profiles over open, level ground with a minimum of instrumentation.

Introduction—In studies of the propagation of sound over ground it has become apparent that the vertical wind and temperature gradients which exist between source and receiver profoundly affect the attenuation of the acoustic signal [*Ingard*, 1953; *Keast* and *Wiener*, 1957]. These gradients produce a gradient of the speed of sound with height which results in refraction of the sound rays. Thus, in order to predict the sound attenuation for a given set of conditions, the wind and temperature profiles over the sound path along the ground must be known. Wind profiles near the ground are of interest also in the study of atmospheric turbulence in the boundary layer, both theoretically [*Davidson* and *Lettau*, 1953] and in relation to the dispersal of atmospheric contaminants [*Cramer*, 1957].

Currently available analytical expressions for the vertical profiles of mean horizontal windspeed [*Sutton*, 1953] contain constants, such as the roughness length and friction velocity. These parameters must either be determined by direct experiment or estimated from tabulations compiled by a number of investigators in this field. Direct measurement of the wind profile requires accurately calibrated and rather costly instrumentation.

The present technique of estimating the wind profile for the first 30 ft above open, level ground is proposed for the many practical situations where one wishes to obtain approximate vertical profiles of mean wind speed with a minimum of instrumentation and computation. Utilizing measurements of a vertical temperature difference between some intermediate heights and of the wind speed near the top of the range of heights of interest, this technique makes use of the fact that temperature differences are usually more easily and accurately measured than differences in wind speed. In addition, the notion of normalizing the mean wind profile to the highest wind speed measured is introduced.

Based on an analysis of several hundred wind and corresponding temperature profiles measured simultaneously over open, level ground, the proposed method is discussed in the following Sections and its limitations are pointed out. Several examples are presented showing a comparison of predicted and measured profiles. Developed for use in estimating outdoor sound attenuation over open, level ground, it is hoped that this technique is of use in other fields as well.

The shapes of mean temperature and wind profiles—The dependence of the general shape of the wind profile near the ground on the thermal stratification is well known. Figure 1 shows idealized profiles of the mean wind speed plotted against height on a logarithmic scale. The profile is generally concave upward for unstable conditions (stability ratio $SR \equiv \Delta T/\bar{u}^2 < 0$), but concave downward for stable conditions ($SR > 0$). For neutral stability conditions ($\Delta T = S = 0$) the profile is very nearly logarithmic. This has been confirmed by numerous investigators, notably *Best* [1935], *Thornthwaite* and *Kaser* [1943], and others.

Idealized temperature profiles near the ground are shown in Figure 2 plotted against height on a logarithmic scale. There is general agreement in the literature [*Sutton*, 1953; *Best*, 1935; *Deacon*, 1949] that the temperature profile is logarithmic for neutral and near-neutral conditions. Concerning the shape of the temperature profile for other conditions of convective stability there is less

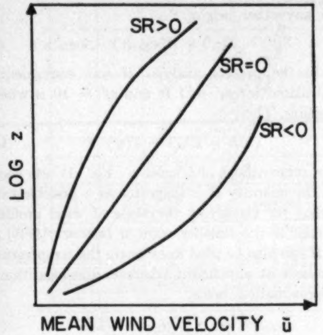

FIG. 1 - Idealized mean wind profiles near the ground

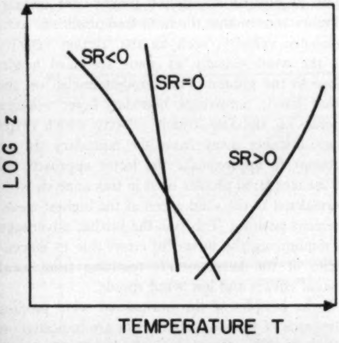

FIG. 2 - Idealized temperature profiles near the ground

agreement. *Lettau* and *Davidson* [1957, appendix to v. 1] has concluded from an analysis of data taken at O'Neill, Nebraska, "that the logarithmic profile form exists in the surface layer only as a transient state, when the thermal stratification passes through neutral." But ***Halstead*** [1954] has analyzed the curvatures of wind and temperature profiles of some of the O'Neill data through heights up to about 20 ft and concluded that both temperature and wind profiles do not depart too far from a logarithmic relation with height except at times of great thermal stability. Examination of the large body of experimental data referred to in this paper which includes all of the O'Neill data tabulated [*Lettau* and *Davidson*, 1957, v. 2] shows that the temperature profile can be approximated by a logarithmic relation in a large number of cases, for both stable and unstable conditions, the cases of strong thermal inversion excepted.

On the assumption that the mean temperature profile measured near the ground over open, level terrain can be approximated by a logarithmic relation, one can use the logarithmic slope of the temperature profile to classify and estimate the corresponding wind profiles near the ground. The method proposed here uses this slope in conjunction with the measured wind speed at a suitable height to estimate the corresponding mean wind profile with the aid of a generalized contour chart. The results obtained show that this is a workable procedure resulting in useful engineering estimates of the wind profiles in many cases.

Measurements of wind and temperature profiles—The following four sets of profile data have been analyzed in the course of developing the profile prediction procedure, providing a total of about 600 pairs of wind and temperature profiles.

(1) Johns Hopkins University measurements [*Lettau* and *Davidson*, 1957; *Johns Hopkins University*, 1953] at O'Neill, Nebraska, from July 29, 1953, to September 8, 1953, consisting of about 300 wind profiles (hourly averages) measured over open, level ground, with corresponding temperature profiles. The ground cover was mowed grass about 0.17 ft high.

(2) Massachusetts Institute of Technology measurements [*Lettau* and *Davidson*, 1957] at O'Neill, Nebraska, from August 4, 1953, to September 8, 1953, consisting of about 200 wind profiles (hourly averages) with corresponding temperature profiles.

(3) Massachusetts Institute of Technology measurements (private communication) at Round Hill, South Dartmouth, Massachusetts, from December 1, 1954, to November 8, 1955, consisting of about 25 wind profiles measured over open, level ground with corresponding temperature profiles. The ground cover was grass about 0.5 ft high.

(4) *Bolt*, *Beranek*, and *Newman*, *Inc.* [1957] measurements in conjunction with sound propagation studies at Deblois, Maine, between September 23 and October 12, 1955, consisting of about 30 wind profiles measured over open, level ground with corresponding temperature profiles measured. The ground cover was grass and low bushes about a foot high.

In addition to the above four sets of data, a set not included in the analysis was used to check the empirical prediction procedure: Texas A & M measurements (private communication) at O'Neill, Nebraska, from July 3 to August 30, 1956, consisting of about 65 wind profiles measured over open, level ground with corresponding temperature profiles.

Analysis of the temperature profiles—Eight sample daytime and nighttime profiles chosen at random from each of the four sets of data are plotted in Figure 3. The ordinate is a logarithmic scale of height z' above ground cover. (The height of the ground cover is defined as the mean elevation of the tops of the vegetation above ground.) This is a simplification made throughout the analysis in order to eliminate the differences in the mean heights of the ground covers at the various measurement locations.

A study of Figure 3 indicates that most of the temperature profiles are roughly logarithmic, at least between one and 10 to 15 ft above ground cover. This has been found to be particularly true when the gradient is negative, as is usually the case during the daytime and, of course, for near-neutral conditions. Two additional profiles are shown which deviate markedly from the logarithmic relation. They illustrate the variability of the profile shapes found especially at night during stable conditions.

If one approximates the temperature profile by a straight line plotted against the logarithm of the height above ground cover, one can define the profile by a constant slope H. Thus, for a given temperature difference at heights z_1' and z_2'

$$H = \frac{T(z_2') - T(z_1')}{\log_{10}(z_2') - \log_{10}(z_1')} \text{ °F} \qquad (1)$$

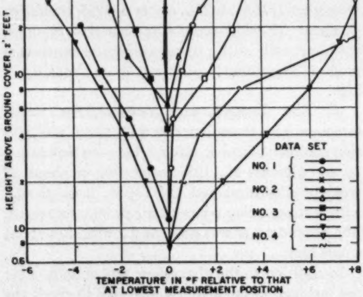

FIG. 3 – Selected measured mean temperature profiles from each of the four data sets

At any other height, z'

$$T(z') - T(z_1') = H[\log_{10}(z') - \log_{10}(z_1')] \qquad (2)$$

In the present analysis H was conveniently calculated for $z_1' = 1$ ft and $z_2' = 10$ ft where possible. Then

$$H = T(z_2') - T(z_1') \text{ °F} \qquad (1a)$$

For other values of z_1' and z_2', Eq. (1) was used.

The quantity H is suggested as a possible candidate for classifying the slope of wind profiles, similar to the stability ratio or *Deacon's* [1949] β.

H can also be used to estimate the temperature gradient at any height wherever the logarithmic approximation holds.

$$\partial T/\partial z = \partial T/\partial z' = H/2.3z' \qquad (3)$$

Analysis of the wind profiles—In the analysis of wind profiles, it is common practice for meteorologists to normalize the measured profiles to some reference velocity, such as the friction velocity or the wind velocity at some standard height close to the ground. The aerodynamicist, on the other hand, normalizes boundary-layer velocity profiles to the free-stream velocity which exists some distance away from the boundary. In an attempt to approximate the latter approach, all of the measured profiles used in this analysis were normalized to the wind speed at the highest measurement position. This has the further advantage of minimizing the spread of errors due to inaccuracies of the anemometers resulting from local ground effects and low wind speeds.

Eight samples of the normalized wind profiles from each of the four sets of data are indicated on Figure 4. (These profiles are not necessarily companion profiles of the temperature profiles shown in Fig. 3.) These profiles are plotted against height above ground cover. In addition, each profile is labeled with the value of H determined from two points on its corresponding temperature profile. The samples on Figure 4 have been chosen to provide a wide range in H, and it is evident from the figure that a correspondingly wide range of profile shapes has resulted. Comparison of Figure 4 with Figures 1 and 2 suggests the possibility of using H, like SR or β, as a parameter associated with the shape of the profile.

The possibility of a correlation between wind profile shape and H is brought out somewhat more clearly in Figure 5. Here, all the profiles plotted on Figure 4 are normalized to the wind speed at the same height, in this case 30 ft above ground cover. (When actual measurements were not

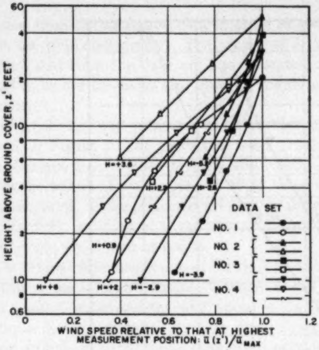

FIG. 4 – Selected measured mean wind profiles from each of the four data sets; the abscissa is normalized to the wind speed at the highest measurement position

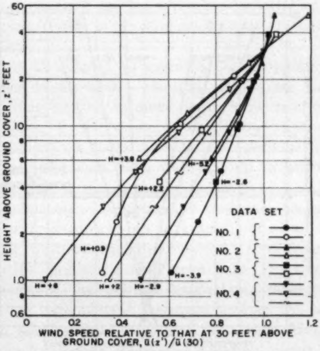

FIG. 5 – Mean wind profiles replotted against wind speed normalized to the wind speed at 30 ft

obtained at 30 ft, the wind speed at this height was interpolated or extrapolated, as required, from the data at the other measurement points.) It is clear from Figure 5 that the steeper profiles which are concave upward are associated with negative values of *H*, and the profiles which are concave downward accompany positive values of *H*. In addition, there is an indication that a relationship exists between the shape of the profile and the magnitude of *H*, as well as its sign, although some exceptions to this are evident.

The results of the analysis of all 600 profile pairs analyzed in the manner outlined above are condensed in the generalized profile prediction contours shown in Figure 6. (Notes on its derivation are given in the Appendix.)

One enters the graph with a known value of *H*, either determined from a known temperature profile, or obtained from a measurement of the temperature difference between two points, in the range between 1 ft and 15 ft above ground cover. The corresponding normalized wind profile is then read from the ordinate scale at the intersections of a vertical line placed at *H* on the abscissa and the families of curves shown for z' = 1 ft, 2 ft, 4 ft, etc., above ground cover. The actual estimated wind profile is then obtained by multiplying the values of normalized wind speed by the mean wind speed at 30 ft, which is obtained by direct measurement. If the wind speed is measured at some other height less than 30 ft, the normalized profile is used to calculate the wind speed that would have been measured at a height of 30 ft and that value is used to obtain the actual estimated profile. If desired, the wind gradient may then be estimated from the profile at any point, most conveniently perhaps by graphic means.

An indication of the accuracy of the proposed method is provided by examining the spread of the data points through which the contours of Figure 6 were drawn as averages. This spread is indicated by the cross-hatched areas and applies to about 80 per cent of the measured points. For $H > +4$ very little data exist, although occasional values of *H* as large as 12 or 15 were encountered. In this region the curves in Figure 6 are shown dashed.

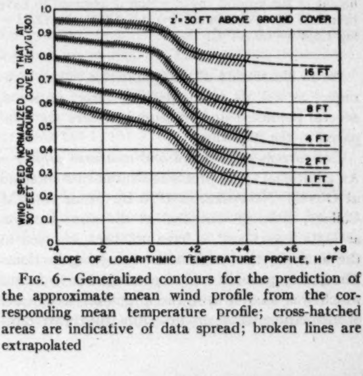

FIG. 6 – Generalized contours for the prediction of the approximate mean wind profile from the corresponding mean temperature profile; cross-hatched areas are indicative of data spread; broken lines are extrapolated

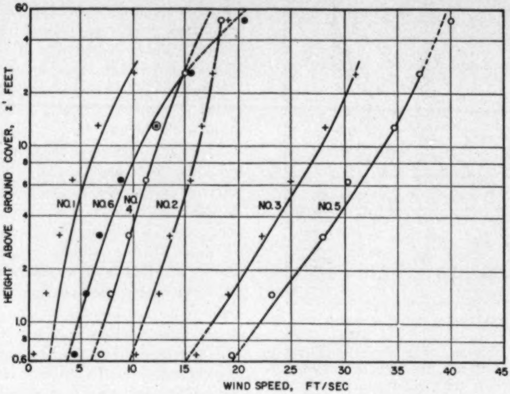

FIG. 7 – Comparison of predicted and measured profiles of mean wind speed; the points indicate measured values

TABLE 1 – *Six test examples*

Example	Date	Time		Measured ΔT between 0.5m + 4m[a]	Calc. value of H	Measured wind speed at 30 ft (interpolated)
	1956	h	m	°C	°F	ft/sec
1	July 6	01	05	+2.55	+4.8	10.2
2	July 11	12	05	−2.53	−4.8	17.7
3	July 14	08	08	−1.28	−2.4	31.2
4	July 23	20	05	+0.44	+0.8	15.2
5	Aug. 7	15	05	−1.77	−3.4	37.5
6	Aug. 25	22	35	+1.49	+2.8	16.0

[a] All quantities measured in metric units were converted to English units. Thus: 0.5m = 1.63 ft; 4m = 13.1 ft; ΔT°F = 9/5 ΔT°C. Subtracting the mean height of the ground cover, which is assumed to have been 0.17 ft, we obtain H °F = 9/5 ΔT°C/(log 12.93 − log 1.46) = 1.9 ΔT°C.

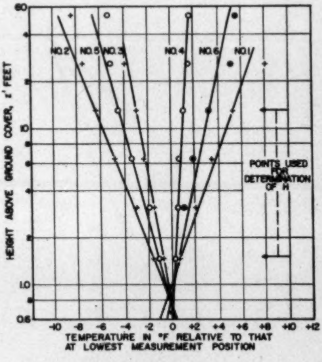

FIG. 8 – Comparison of logarithmic temperature profile relation and observed points

As an illustration of the application of this technique, as well as of the possible errors involved, several predicted and measured profiles are compared in the following.

Comparison of predicted and measured profiles—An additional set of profile measurements obtained at O'Neill, Nebraska, in 1956 by Texas A & M College, although obtained at the same location as Data Sets 1 and 2, have not been included in the analysis discussed in the foregoing Sections. Thus, they provide an independent body of data which was used to test the proposed techniques of estimating wind profiles from measured temperature differences between two points and the measured wind speed at a third.

Six examples have been chosen at random from these data to provide a wide range of wind speed and temperature conditions. For each of these examples, the measured temperature difference between the 4m and the 0.5m measurement heights has been used to calculate H. In addition, the value of the wind speed at 30 ft was interpolated from the measured data. Table 1 lists the information obtained from the measured data in order to construct the predicted profiles. The values of H in °F calculated from the data are also indicated in the table, as are the dates and times of the measurements.

The predicted and measured wind profiles are plotted in Figure 7. The predicted wind profiles were obtained from Figure 6, using the values of H and the values of wind speed at 30 ft listed in the above table. These predicted profiles are shown as solid lines on Figure 7, the actual measured wind speeds are shown as points.

It is evident from inspection of Figure 7 that the greatest errors arise in Example 1, where H has a large positive value and the wind speed is low. In Example 3, the predicted profiles also indicate higher values of wind speed than were actually measured, although the errors are smaller. For the rest of the examples, the deviation between the measured points and the predicted profiles is ten percent or less. Note that the gross curvatures of the measured profiles which are important for the computation of the wind gradient are predicted correctly.

It is of interest to examine the temperature profiles in the above examples and to see how well they fit the assumed logarithmic relation. In Figure 8, the assumed logarithmic relations (solid lines) are compared with the experimentally determined points. It is seen that up to heights of about 15 ft the agreement is fair.

Conclusions—The procedure described permits one to approximate, up to a height of about 30 ft, the mean wind profiles over open, level ground with low, uniform ground cover from (1) a measurement of the vertical temperature difference between two points in the range between 1 ft and 15 ft above ground cover, and (2) a measurement of the mean wind speed at a height of about 30 ft or less.

In carrying out this procedure, the assumption has been made that the temperature profile can be approximated by a logarithmic function. Its logarithmic slope is used to estimate and classify the corresponding mean wind profile. Experimental evidence indicates that this is reasonable in many cases, especially for unstable and near-neutral temperature stratification when errors in estimating the wind profile appear tolerable for many applications. For stable conditions, however, the temperature profile may depart appreciably from the logarithmic relations; also, the errors in estimating the wind profile are large under those conditions.

If desired, estimates of the wind gradients near the ground can be obtained from the estimated wind profile. The logarithmic temperature profile approximation yields estimates of the temperature gradient as a function of height. These gradients have been found useful for the estimation of the attenuation of sound propagated along the ground. Perhaps the estimated wind profiles and the gradients obtained therefrom are also adequate for other applications, where the micrometeorological instrumentation necessary for the direct measurement of wind profiles is too expensive or cannot be used for one reason or another.

Acknowledgments—All profile data analyzed in the course of this study, Data Set 4 excepted, were kindly provided prior to their publication by H. E. Cramer of the Round Hill Field Station of the Massachusetts Institute of Technology, South Dartmouth, Massachusetts. This assistance, and the help and encouragement extended the authors by him and his staff throughout this study are gratefully acknowledged. This work was supported by the U. S. Signal Corps under Contract DA-36-039 SC-64503 with Bolt, Beranek, and Newman, Inc.

APPENDIX

The detailed procedure followed in the preparation of Figure 6 is as follows: Values of H were obtained from the temperature profiles corresponding to each wind profile. For this purpose, temperature readings at the following heights were used: (a) 40 cm and 320 cm for Data Set 1; (b) 2m and 4m for Data Set 2; (c) 1.5m and 3m for Data Set 3; and (d) 0.75 ft and 8 ft for Data Set 4.

Then, for each wind profile, the wind speeds at the various heights were normalized to that at the greatest height where measurements were obtained (as in Fig. 4). The resulting normalized profiles were then plotted as points on a sheet similar to Figure 6, except that the ordinate was different in each case, namely, (a) $V(z')/V(21\text{ ft})$ for Data Set 1; (b) $V(z')/V(52\text{ ft})$ for Data Set 2; (c) $V(z')/V(38\text{ ft})$ for Data Set 3 and (d) $V(z')/V(30\text{ ft})$ for Data Set 4.

Similarly, the height parameters z' were different in each case because the measurement heights differed. An average curve for each measurement height was then drawn through the points on these figures, resulting in four sets of curves similar to those in Figure 6. Average profiles for different values of H could then be constructed from these average curves. From these average profiles, it was possible to interpolate normalized wind speeds at the same heights for all the sets of data and to renormalize these to the interpolated value of the wind speed at $z' = 30$ ft. Figure 6 was constructed from these interpolated, renormalized values.

Characteristics of Waves Generated by a Local Disturbance

J. E. PRINS

Abstract—Waves generated by an initial local elevation or depression of uniform height were investigated in a two-dimensional model. The height of the elevation or depression, the extent of the disturbed area, and the water depth were varied. The model data were compared with the theories of *Unoki* and *Nakano* [1953] and *Kranzer* and *Keller* [1955]. It was found that within certain limits of water depth, height, and extent of disturbed area the wave characteristics, such as phase periods and interference pattern, could be described reasonably well. The magnitude of the wave heights was not predicted satisfactorily.

Introduction—The purpose of the investigation was to determine if the characteristics of waves caused by a local disturbance of the water surface could be formulated reliably by theory. The practical value of this is found in its application in the prediction of the wave motion resulting from an underwater seismic disturbance or a near-surface or underwater explosion. A literature survey is given by *Prins* [1956], in which three groups of solutions are considered: (1) initial elevation or depression of the surface without initial velocity, (2) undisturbed surface with an initial distribution of a surface impulse, and (3) undisturbed surface with an initial distribution of a submerged impulse (underwater explosion).

Owing to the practical limitations of the model study the following reported investigations were restricted to group (1), considering only the two-dimensional case of an elevation or depression of uniform height.

Experimental equipment and procedure—The model investigations were carried out in a flume one foot wide by 60 ft long. At one end of the channel it was possible to create a free elevated or depressed area with all the water particles effectively at rest. At the opposite end of the channel a wave absorber was installed. The vertical movement of the water was recorded simultaneously at five places along the channel ($\eta - t$ curves). The model set-up is given in Figure 1. The extent L and the height Q of the elevations or depressions and the water depth h were varied by steps: $h = 2.3$, 0.5, 0.35, and 0.2 ft; $L = \frac{1}{3}$, 1, and 2 ft; $Q = \pm 0.1$, ± 0.2, and ± 0.3 ft.

MATHEMATICAL DESCRIPTION OF THE PHENOMENA

The formulation of the problem in regard to the model investigation was to describe the water-surface position with respect to the undisturbed water level as a function of place and time when a disturbance consisting of an elevation or depression with a constant height Q extended over a length L in a two-dimensional system of water depth h was released. In general

$$\eta = f(Q, L, h, x, t) \tag{1}$$

The two following cases given in the literature are applicable to the given conditions.

Unoki-Nakano equation—The two-dimensional case of an initial elevation of a finite area in water of infinite depth has been formulated by ***Unoki*** and *Nakano* [1953] as follows: initial conditions at $t = 0$: velocity potential, $\phi_0 = 0$; elevation, $\eta_0 = Q$ at $-L < x < L$, and $\eta_0 = 0$ at $|x| > L$.

Solution

$$\eta = \frac{4Q\,x^{\frac{1}{2}}}{\pi^{\frac{1}{2}} g^{\frac{1}{2}}\, t} \sin\left(\frac{gt^2}{4x} \cdot \frac{L}{x}\right) \cdot \cos\left(\frac{gt^2}{4x} - \frac{\pi}{4}\right) \tag{2}$$

for $x \gg L$.

Wave characteristics: the phase period is defined by $\cos(gt^2/4x - \pi/4)$ so that

$$T = \frac{4\pi x}{gt}, \lambda = \frac{8\pi x^2}{gt^2}, C = \frac{2x}{t}\left(= \sqrt{2\pi}\right) \tag{3}$$

The amplitude variation of the waves is defined by $\sin\,(gt^2/4x)\cdot(L/x)$, with the qualities

$$T_1 = \frac{4\pi x}{gt} \cdot \frac{x}{L}, \lambda_1 = \frac{8\pi x^2}{gt^2} \cdot \frac{x}{2L},$$

$$C_1 = \frac{x}{t}\left(= \frac{1}{2}\sqrt{\frac{g\lambda}{2\pi}}\right) \tag{4}$$

Kranzer-Keller equation—The three-dimensional case of an initial elevation or depression of a finite area in water of finite depth has been formulated by *Kranzer* and *Keller* [1955] as follows: initial conditions at $t = 0$: shape of elevation, $E(r)$; elevation at the origin, ζ_0; effective radius of displacement, R.

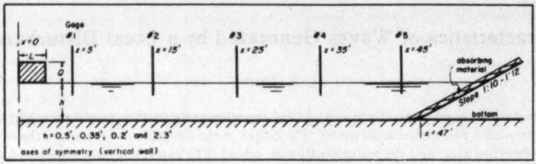

FIG. 1 – Model set-up

Solution

$$\zeta_e = \zeta(r, t) \approx \frac{\zeta_0 R}{r} \mathrm{B} \cos 2\pi \left(\frac{t}{T} - \frac{r}{\lambda}\right) \quad (6)$$

for $r \gg R$ and $B = 0$ at $r > \sqrt{gh} \cdot t$, in which R is defined by

$$\tfrac{1}{2} |\zeta_0| R^2 = \int_0^\infty |E(r)|\, r\, dr \text{ and}$$

$$\pi |\zeta_0| R^2 = \text{displaced volume} \quad (7)$$

Wave characteristics: the linear theory of surface waves is applied and the functions are expressed in terms of the auxiliary variable $\sigma = 2\pi h/\lambda$, which is defined as the unique non-negative root of the equation

$$\phi(\sigma) = \tfrac{1}{2} \sqrt{\frac{\tanh \sigma}{\sigma}} + \frac{1}{2 (\cosh \sigma)^{3/2}} \sqrt{\frac{\sigma}{\sinh \sigma}} = \frac{r}{\sqrt{gh} \cdot t} \quad (8)$$

The phase period is defined by $\cos 2\pi (t/T - r/\lambda)$, so that

$$T = \frac{2\pi}{\sqrt{\frac{g\sigma}{h}} \tanh \sigma}, \quad \lambda = \frac{2\pi h}{\sigma},$$

$$C = \sqrt{\frac{g\lambda}{2\pi} \tanh \frac{2\pi h}{\lambda}} \quad (9)$$

The amplitude variation of the waves is defined by the B-term, which is expressed as follows

$$B = \frac{1}{\zeta_0 R h} \bar{E}\left(\frac{\sigma}{h}\right) \sqrt{\frac{\sigma \phi(\sigma)}{-\phi'(\sigma)}} \text{ at } r < \sqrt{gh} \cdot t \quad (10)$$

in which $\bar{E}(\sigma/h)$ is the zero-order Hankel transformation of the initial elevation $E(r)$ and is given by

$$\bar{E}\left(\frac{\sigma}{h}\right) = \int_0^\infty E(r) J_0 \left(\frac{\sigma r}{h}\right) r dr \quad (11)$$

For water of finite depth σ/h becomes $gt^2/4r^2$ and the equation turns into

$$\zeta_e = \zeta(r, t) \approx \frac{\zeta_0 R}{r} B \cos \frac{gt^2}{4r} \quad (12)$$

with wave characteristics

$$T = \frac{4\pi r}{gt}, \quad \lambda = \frac{8\pi r^2}{gt^2}, \quad C = \frac{2r}{t} \sqrt{\frac{g\lambda}{2\pi}} \quad (13)$$

$$B = \frac{\sqrt{2}}{\zeta_0 R} \cdot \frac{gt^2}{4r^2} \cdot \bar{E}\left(\frac{gt^2}{4r^2}\right) \quad (14)$$

COMPARISON OF EXPERIMENTAL RESULTS AND THEORY

The experimental data are given as $\eta - t$ curves at a fixed place from which the required quantities can be deduced, such as phase period, phase zero points, amplitude envelope zero points and wave amplitudes.

The equation given by *Unoki* and *Nakano* [1953] is directly applicable to the investigated case for infinite water depth. As the waves are dispersive there will be a region where the water is deep enough to be considered as infinite with respect to the waves ($h/\lambda > 0.5$).

The equation of *Kranzer* and *Keller* [1955] deals with the three-dimensional case. The two terms determining the oscillating system can be applied as well to the two-dimensional case. However, the wave amplitudes can not be calculated. For the shape of the disturbance $E(r)$ the elevation of constant height has to be introduced.

Special attention has to be given to the leading part of the generated wave train. The characteristics of the leading disturbance are dependent on the ratios Q/h and L/h, as is shown schematically in Figure 2.

The following types of the leading part could be distinguished: (1) leading wave with oscillatory characteristics, being part of the dispersive wave pattern (O), (2) leading wave with solitary wave

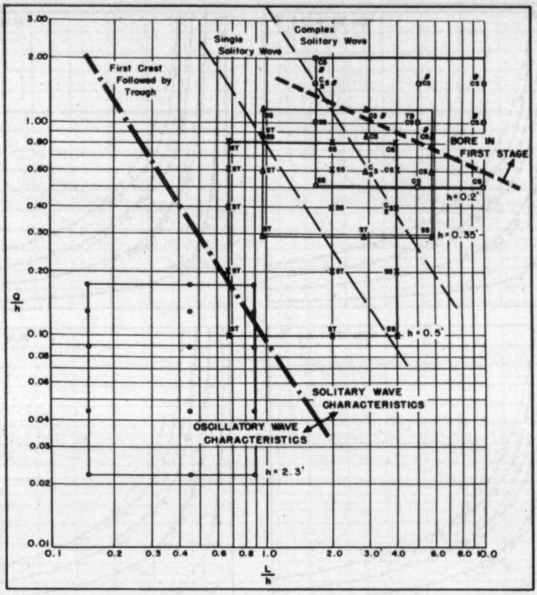

FIG. 2 – Relation between *L/h*, *Q/h* and the characteristics of the leading wave in the case of elevation

characteristics with respect to its velocity of propagation, followed by a trough connecting it with the dispersive wave pattern (ST), (3) leading wave being a single wave with solitary wave characteristics, separated from the dispersive wave pattern by a more or less flat part at the still-water-level (SS), and (4) leading part being of complex form, which, while traveling outward, breaks up into a few waves with solitary wave characteristics separated from the dispersive wave pattern (CS).

For certain conditions either a bore (B) or a top bore (TB) occurred which did not seem to affect appreciably the type of leading wave.

The following is restricted to the case for which the leading disturbance has the characteristics of an oscillatory wave. The other types have been discussed extensively by *Prins* [1958].

Phase period—In the $t - T$ plane the theoretical curves for the $t - T$ relation at constant x can be plotted according to (3) at infinite depth, and to (9) at depth h.

The curve for finite depth starts to deviate from the infinite depth curve at $h/\lambda = 1.0$ and at large periods approaches $\sqrt{gh}$. The evaluation of this curve can be made by using (8) for σ as a function of $x/\sqrt{gh}\cdot t$.

Eq. (8) also may be written as $x = C_{gr}\cdot t$ (15) in which

$$C_{gr} = \tfrac{1}{2}\left[1 + \frac{\dfrac{4\pi h}{\lambda}}{\sinh\dfrac{4\pi h}{\lambda}}\right]\left(\tanh\frac{2\pi h}{\lambda}\right)\cdot C_0$$

$$\text{and } C_0 = \frac{g}{2\pi}\cdot T$$

The ratio C_{gr}/C_0 as a function of h/λ_0 is tabulated by *Wiegel* [1954].

The formula $x = C_{gr}t$ shows that a wave reach-

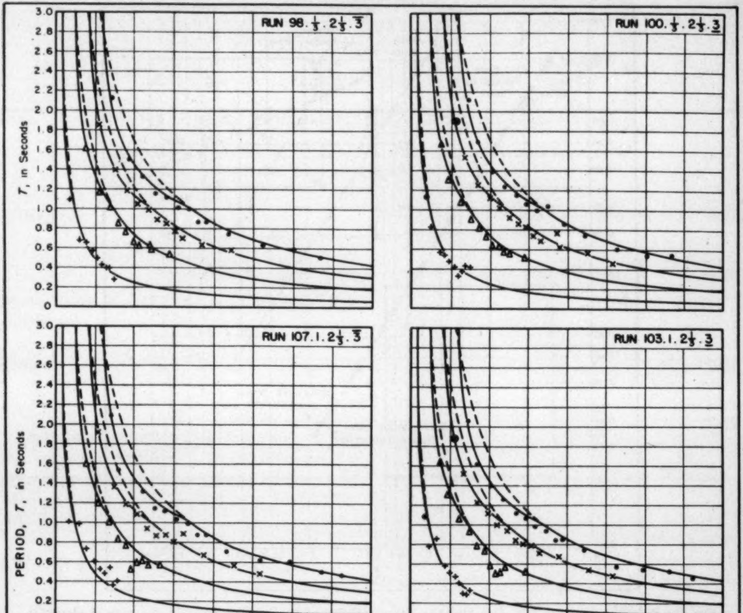

FIG. 3 – t-T relationship for water depth $h = 2.3'$, dashed line $T = 4\pi x/gt$ (infinite depth theory), solid lines Kranzer and Keller theory for $h = 2.3'$

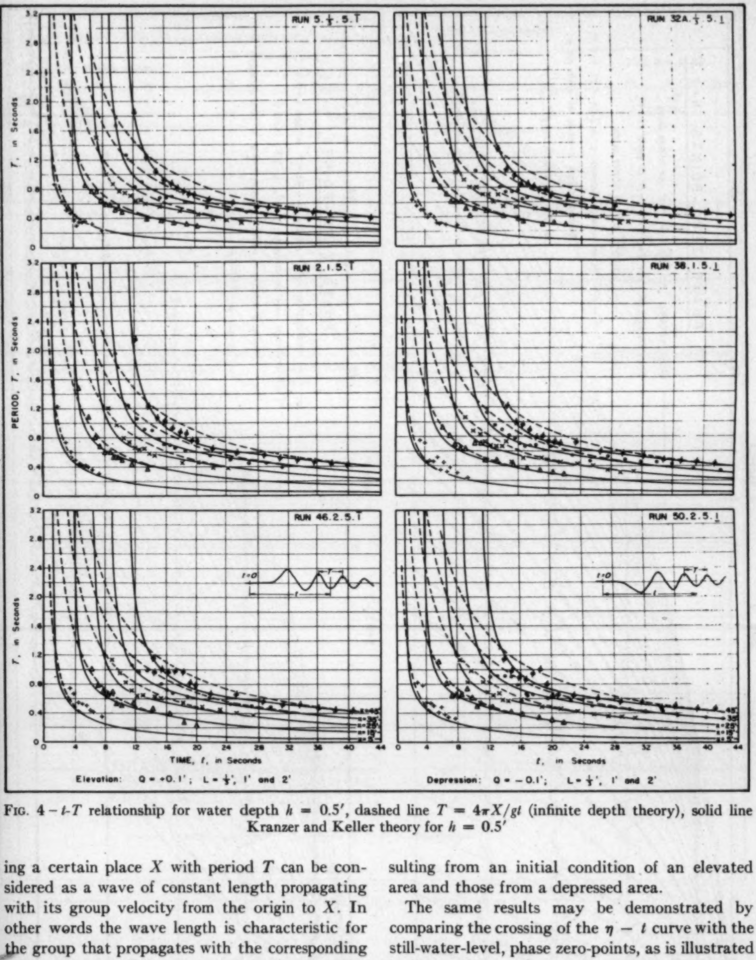

FIG. 4 – t-T relationship for water depth $h = 0.5'$, dashed line $T = 4\pi X/gt$ (infinite depth theory), solid line Kranzer and Keller theory for $h = 0.5'$

ing a certain place X with period T can be considered as a wave of constant length propagating with its group velocity from the origin to X. In other words the wave length is characteristic for the group that propagates with the corresponding group velocity. This was noted by *Lamb* [1956, art. 238–241 and 255] for water of infinite depth.

Figures 3 and 4 show the agreement of the experimental values with the theory. It proves that the deviations increase with increasing L. There is no essential difference between the waves resulting from an initial condition of an elevated area and those from a depressed area.

The same results may be demonstrated by comparing the crossing of the $\eta - t$ curve with the still-water-level, phase zero-points, as is illustrated in Figure 5.

The amplitude envelope curve—The relatively long periodic phenomenon defining the amplitude variation can be determined by considering the location of the zero points. It has also a dispersive character.

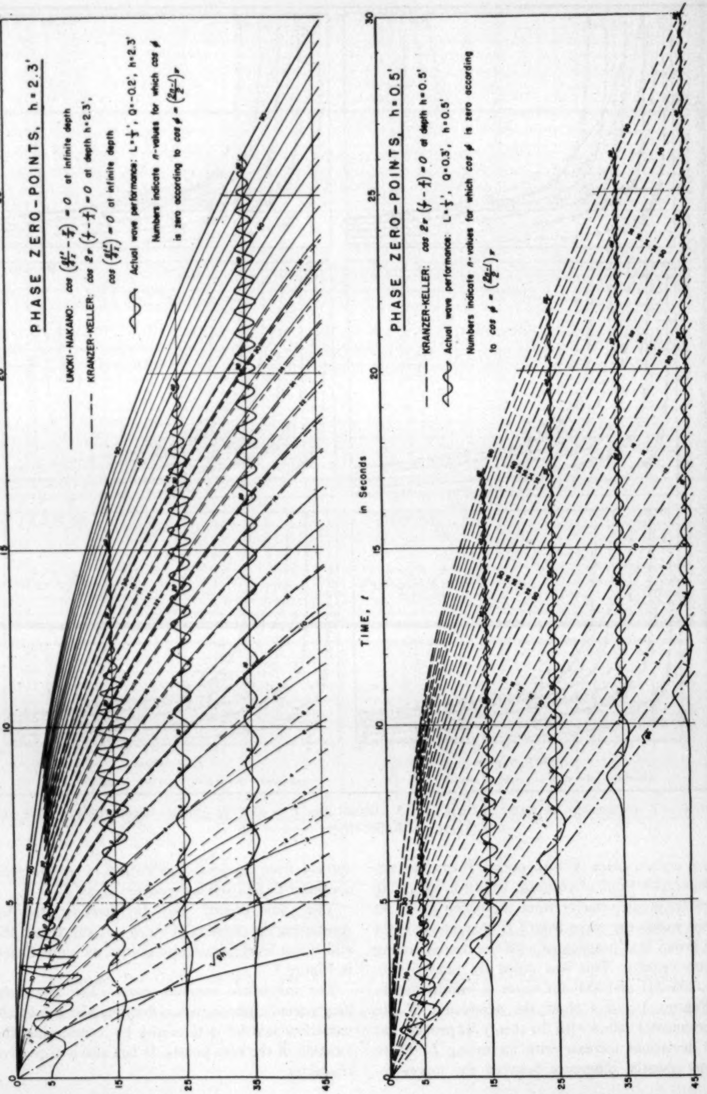

FIG. 5 – Phase zero-points, h = 2.3' and 0.5'

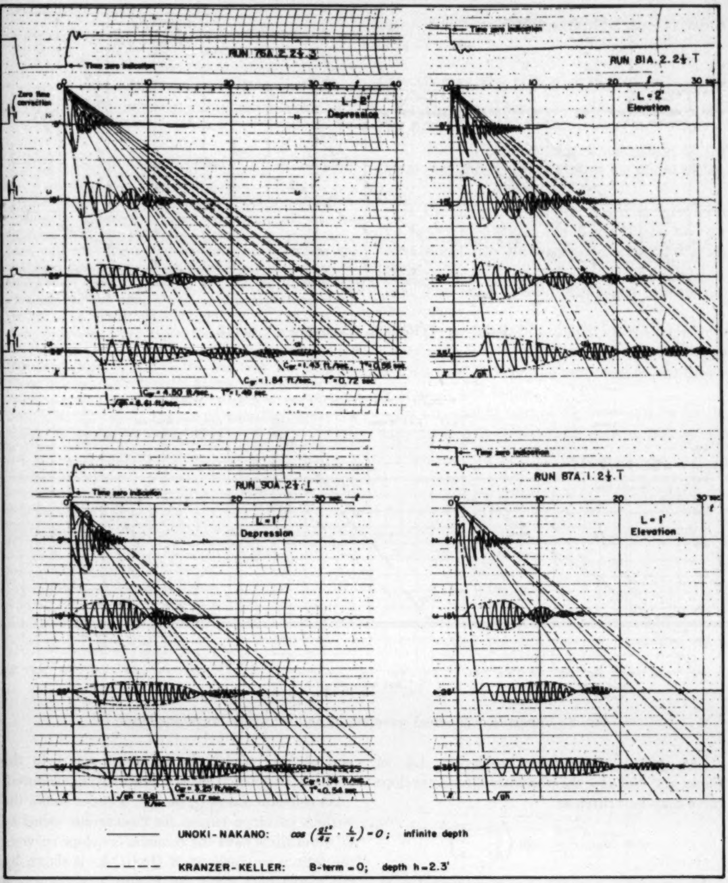

FIG. 6 – Amplitude envelope zero-points, $h = 2.3'$

The location of the envelope zero point is given by Unoki and Nakano as sin $(gt^2/4\ x\cdot L/x) = 0$, or $x/t = \sqrt{L}\ \sqrt{g/4n\pi}$ at $n = 0, 1, 2, \cdots$. In the $x - t$ plane the velocity of propagation of the zero points should be constant and proportional to $\sqrt{L}$.

According to Kranzer and Keller the envelope zero points will occur when $B = 0$. By introducing the initial conditions of the model, this will happen when the Bessel function of the first order $J_1[(\sigma/h)L] = 0$. At $\sigma > 3$ the position of the zero points proves to be independent of the water depth and the velocity of propagation (x/t) proportional to $\sqrt{L}$.

The experiments show a good agreement with the condition of Unoki and Nakano as is illustrated by Figure 6, especially at the larger extents of the disturbed area.

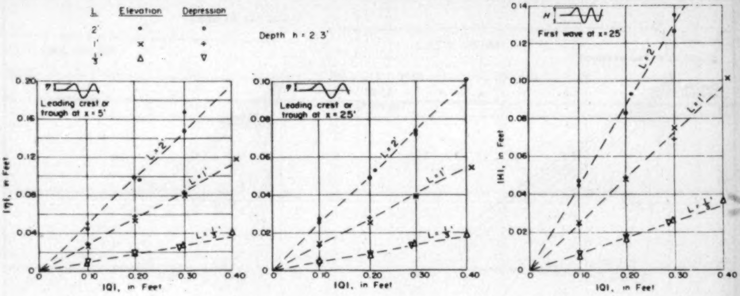

FIG. 7 – η—Q Relation at constant x, t, and L

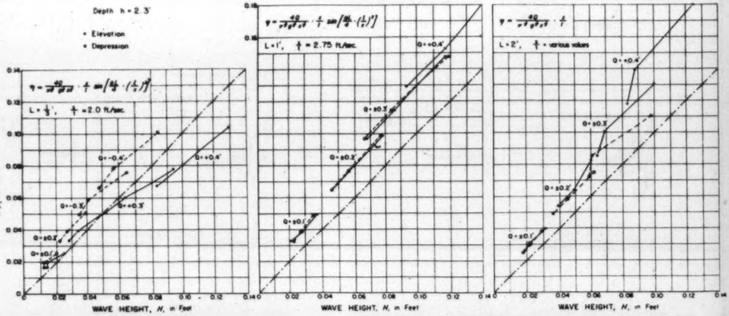

FIG. 8 – Comparison of actual wave height and calculated wave amplitude

The phase amplitudes—Considering (2) of Unoki and Nakano, the phase amplitude envelope curve may be written as

$$\eta = \text{const.}\,\frac{Qx^{\frac{1}{2}}}{t}\cdot\sin\left(\frac{gt^2}{4x}\cdot\frac{L}{x}\right)$$

At constant x, t, and L, η is proportional to Q. In regard to the leading crest or trough it was found that η was directly proportional to Q. There was no difference between the case of an initial elevation or depression. Figure 7 presents some model data, and Figure 8 presents the relationship of actual wave heights to calculated amplitude.

At constant x/t (elimination of the sine term), L, and Q, η is proportional to $x^{-\frac{1}{2}}$. At depth h = 2.3 ft the results shown in Table 1 were obtained for the ratios of the amplitudes η_{15}/η_{25}, η_{15}/η_{35}, and η_{25}/η_{35}, where the subscript refers to the position X at which the amplitudes were measured.

At constant x and Q, the $\eta - t$ curve shows the various envelope curves for the various values of L. All of these have the common envelope curve of the form η = constant $\times\, Q\, x^{\frac{1}{2}}/t$. As is shown by the model data given by Figure 9, there was a definite tendency for a common envelope curve to exist for different values of L. In considering the energy distribution within the wave pattern, together with the area of disturbance, it was found that when the disturbance was extended vertically, the character of the wave pattern was maintained with the amplitudes being proportional to the vertical change of disturbance. When the disturbance was extended horizontally, the wave pattern changed its appearance, but the amplitudes did not exceed those of the common envelope

TABLE 1

L	Theoretical ratio		
	η_{15}/η_{25} 1.29	η_{15}/η_{35} 1.52	η_{25}/η_{35} 1.18
ft			
2	1.53[a]	1.76	1.16
1	1.35	1.69	1.24
$\frac{1}{3}$	1.39	1.60	1.15

[a] Average from values at $Q = +0.4$ through $Q = -0.4$. The agreement was not satisfactory. It was not expected that the theoretical amplitudes would compare well with the actual measurements, because the envelope amplitude in the theoretical case was different from the actual values (see Fig. 6). By properly choosing the x/t value it was possible to obtain better results. The actual wave heights H at constant x/t were compared with twice the amplitude calculated by the use of (2). This has been shown in Figure 8 (for the plot for $L = 2$ ft, the sine term was assumed to be unity). Again there is little or no difference between the data for an initial condition of elevation or an initial depression. The actual values of H did not reach the theoretical values of 2η.

curve, which was independent of the variation of L.

CONCLUSIONS FOR $Q/h < 0.18$ AND $L/h < 0.9$

(1) The generated wave pattern was of a dispersive character.

(2) The variation of height and extent of the initial disturbance did not affect the phase velocities.

(3) The phase periods were found to agree with the theory of *Kranzer* and *Keller* [1955], and for 'deep water' with the theory of *Unoki* and *Nakano* [1953].

(4) The wave pattern showed an interference phenomenon.

(5) The position of the amplitude envelope zero-points was found to be well expressed by the theory of Unoki and Nakano and fairly well by the theory of Kranzer and Keller.

(6) The leading part of the wave pattern for the case of an initial elevation showed exactly the

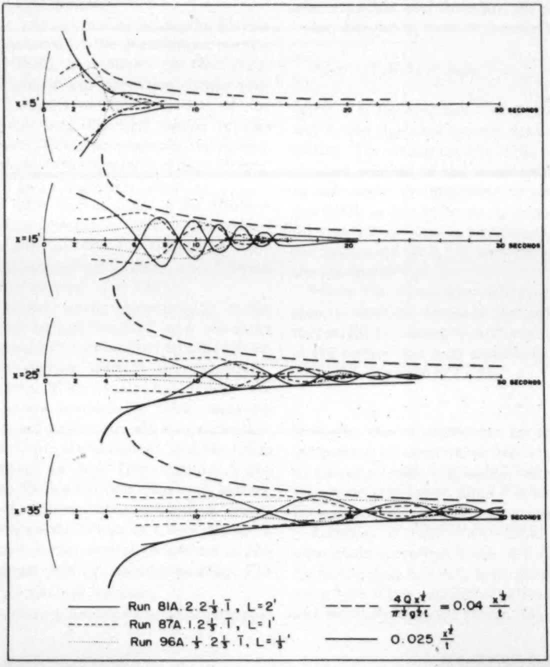

FIG. 9 – Amplitude envelope curves with constant Q and variations of L

negative performance of the waves generated by an initial depression ($\eta_{elev} = -\eta_{depr}$).

(7) The amplitudes of the leading waves were found to be directly proportional to the height of the initial disturbance.

(8) The wave amplitudes did not show a satisfactory agreement with the theoretical values according to Unoki and Nakano. In general the measured values were found to be smaller than the theoretical values.

Acknowledgment—The investigations described in this paper were conducted by the author while a Fulbright Research Scholar at the Wave Research Laboratory of the Institute of Engineering Research, University of California, Berkeley. The work was performed under the sponsorship of the Office of Naval Research.

The author wishes to express his appreciation to J. W. Johnson for facilitating the investigations and to R. L. Wiegel for his suggestions and critiques.

An Interpretation of the Transverse Component of the Geomagnetic Electrokinetograph Readings in the Florida Straits off Miami

FRANK CHEW

Abstract—The transverse component of the Florida Current was studied by the Geomagnetic Electrokinetograph (GEK), the use of which is reviewed for the Florida Current. Based on 422 GEK fixes taken over a five-year period, including three special time series, two constituent surface transverse components are shown to exist, both of which involve a return flow at greater depths. One constituent resembles the downstream advection of an internal wave with its current reversing sign every 8 to 16 hours. The other is a diverging surface flow in the free stream apparently explainable in terms of the vorticity equation.

Introduction—*Pillsbury* [1880] studied the transverse motion in the Florida Current by relating the current width to the Moon's declination. *Parr* [1937] described his study of transverse component in terms of 'transverse extrusion.' Careful navigators of the current are also aware of transverse motion; many charts, for example, U.S.C.& G.S. chart 1112, show current arrows at an angle to the longitudinal direction.

Consecutive velocity profiles across the Florida Current, as measured by the geomagnetic electrokinetograph (GEK), have shown complex variations in longitudinal and transverse components. This paper attempts an interpretation of the transverse component. The first section reviews the validity of GEK measurements in the Straits. The second considers the reduction of data. Presentation of data and a discussion follow.

Validity of GEK measurements in the Straits—The use and interpretation of GEK measurements have been treated by *von Arx* [1950] and more generally by *Longuet-Higgins*, *Stern*, and *Stommel* [1954, hereafter referred to as LSS].

Let the essential electric characteristics of the Florida Current be approximated by a two-layer system contained in a non-conducting channel: an upper, faster, uniform current over a slower, uniform current. When their thicknesses are separately uniform horizontally, GEK measurements in the x and y directions will bear a constant ratio to those of the actual current, and the GEK current directions are real. This condition is not realized in the Florida Current. However, barring windage effect, any consistent pattern of transverse GEK component involving a sign change is real, fluctuation in the vertical component of the Earth's magnetic field H_z notwithstanding. For simplicity, H_z is assumed constant.

To see this clearly, consider the GEK potential in the y direction as given by LSS

$$E_y = \frac{\partial\varphi}{\partial x} S_x + \frac{\partial\varphi}{\partial y} S_y + V_x H_z S_y - V_y H_z S_x \qquad (1)$$

(always for zero cable droop and vertical motion), where S_x, S_y and V_x, V_y are distances between towed electrodes, and speeds relative to the Earth along the x and y directions, respectively; and where the first two terms are the potential in the water. For the S_y term, it is given by

$$\frac{\partial\varphi}{\partial y} S_y = -V_x H_z S_y - \rho i_y S_y \qquad (2)$$

where ρ is the electrical resistivity of the water and i_y the electrical current density in the y direction. The strong current shear observed in the Current consists of the term $(\partial v_y/\partial x)$ and thus cannot affect the alignment of electrodes towed due north or south; hence S_x is zero in (1). That (2) may not be zero in the Straits merely affects the magnitude of E_y; it does not effect an E_y in the absence of V_x.

Where the (vertically) averaged current $\overline{V}$ is high, a direction change in the surface GEK current might be caused by a change in the speed V of the surface skin layer relative to $\overline{V}$ as given by LSS in their equation 2.2.13

$$\rho i_x = (V - \overline{V}) H_z \qquad (3)$$

However, this is improbable for the longitudinal component as observation has always shown V to exceed $\overline{V}$; and it is highly improbable for the transverse component since $\overline{V}$ is always near zero because of the return flow at greater depth.

Reduction of GEK data—GEK measurements were made according to *von Arx* [1950] following his sailing plan A-2 with fixes about 40 min apart using both Navy demolition cables (balsa buoyed) and neutrally buoyant cables. Measurements are therefore subject to windage but free from cable droop. To correct for windage, the method of *Knauss* and *Reid* [1957, hereafter referred to as KR] is used. Since the conditions KR assumed do not all apply to the Florida Current, it is desirable to restate the windage problem for the Florida Current.

The base course of the research vessel is usually south of east or west to offset the current drift; hence the ship's track over bottom is generally due east or west. The potential measured when heading east is, in KR notation

$$E_x = \frac{\partial\varphi}{\partial x} S_x + \frac{\partial\varphi}{\partial y} S_y' - V_y H_z S_x + V_x{}^* H_z S_y' + V_x H_z S_y' \quad (4)$$

On the two fix courses, the measured potentials are

$$E_y = \frac{\partial\varphi}{\partial x} S_x' + \frac{\partial\varphi}{\partial y} S_y - V_y{}^* H_z S_x' + V_x H_z S_y - V_y H_z S_x' \quad (5)$$

$$E_{-y} = \frac{\partial\varphi}{\partial x} S_x' - \frac{\partial\varphi}{\partial y} S_y + V_y{}^* H_z S_x' - V_x H_z S_y - V_y H_z S_x' \quad (6)$$

[a] The hour zero includes the interval from 0–59.9 minutes plus the interval in excess of 12 hr.

where the primed letters represent those components of the vector separation of the electrodes that are perpendicular to the ship's course, and the asterisked letters, the speed of the vessel relative to water. Following *von Arx* [1950], the zero point is

$$\tfrac{1}{2}(E_y + E_{-y}) = \frac{\partial\varphi}{\partial x} S_x' - V_y H_z S_x' \quad (7)$$

The potential $\bar{E}_x$, the value used in computing V_y in (8), is

$$\bar{E}_x = E_x - \tfrac{1}{2}(E_y + E_{-y}) \quad (8a)$$

Or

$$\bar{E}_x = \frac{\partial\varphi}{\partial x}(S_x - S_x') - V_y H_z (S_x - S_x') + V_x{}^* H_z S_y' \quad (8)$$

after dropping the small terms involving S_y'. The potential $\overline{E}_y$, the value used in computing V_x in (5), is obtained by the subtraction of (7) from E_y,

[c] See Table 2, footnote b.

or

$$\overline{E}_y = \frac{\partial\varphi}{\partial y} S_y - V_y{}^* H_z S_x' + V_x H_z S_y \qquad (9)$$

Solving (8) and (9) for V_y and V_x respectively, one has

$$V_y = -\overline{E}_x/(S_x - S_x')H_z + (1/H_z)\frac{\partial\varphi}{\partial x} + V_x{}^* S_y'/(S_x - S_x') \quad (10)$$

and

$$V_x = \overline{E}_y/(H_z S_y) - (1/H_z)\frac{\partial\varphi}{\partial y} + V_y{}^* S_x'(1/S_y) \qquad (11)$$

The two second terms in (10) and (11) are independent of windage and electrode spacing and are dependent solely on the environment; they can be considered constants and be absorbed in their respective first terms as far as windage is concerned. Eq. (10) differs from KR's in another aspect: $(S_x - S_x')$ instead of S_x in the denominator. Usually, S_x' is less than 0.1 S_x. KR indicated that the ratio of S_y' to S_x is 0.05 for 50 pct cable immersion, a vessel speed of 9 knots and wind of 12 m/s. For 7-knot speed of our vessel and for the same wind speed and immersion, the ratio is 0.07. The last term in (10) is thus $(0.075)V^*$ compared

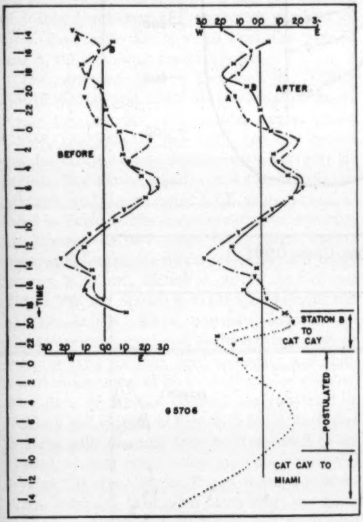

FIG. 2 – Observed and corrected transverse component, Cruise G5706

in addition to the question of wind measurement, there is considerable uncertainty regarding the effect of the sea state on both the drag coefficients and on the immersion of the cable. Thus, one is justified in using the values of KR windage correction.

The direction of the spurious component V_s caused by windage shall be downwind and its magnitude shall be

$$V_s \text{ (cm/s)} = 0.7\, W \text{ (m/s)} \qquad (12)$$

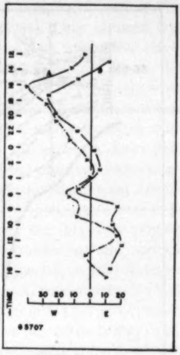

FIG. 3 – Corrected transverse component, Cruise G5707

where the factor 0.7 is the average of the two sets of KR data and W is the wind speed.

Local surface wind drift is subtracted from GEK measurements, in many instances, to study variations that are independent of local winds. As an approximation, the wind drift is taken as two per cent of the wind strength and directed at 45° to the right of the downwind direction. No allowance is attempted for coastal effect nor for complication from changing local winds [*Bowden*, 1953]. The adopted drift correction is often three times that for windage.

The wind drift correction is crude. This could be critical as in Cruise G5707 when winds exceeded 10 m/s on the second day. On calmer days, as in Cruise G5706, and when applied to a longer series, this is fortunately not significant.

The data—All GEK measurements made between latitudes 25° 30′ and 25° 57.9′N during the period December 22, 1952, to May 7, 1957, are used; 422 measurements are thus available.

To explore the relation of GEK data to direct tidal effect, uncorrected data are used in two groups with longitude 79° 45′W as the dividing line. Table 1 and Figure 1 summarize the arithmetically averaged north and east components according to observation hour with respect to Miami Beach predicted high water.

To avoid possible bias introduced by corrections, the basic data are regrouped on a time basis; one group is used corrected while the other is used uncorrected. They are arithmetically averaged

FIG. 5 – Corrected GEK profiles of Cruises T331 and T358b, May 5 and October 24, 1953, respectively

with respect to their geographic locations and the results are listed in Tables 2 and 3 for data collected before and after June 1956 respectively. To assure that the result of Table 2 is not caused by local winds but may reflect the behavior of the Florida Current, local winds at cruise time are tabulated in Table 4. The winds are composites of shipboard observation, synoptic weather reports and winds at the tide stations at Miami Beach and Cat Cay. Considering the windage and wind drift corrections, one may label all winds clockwise from northwest to southeast inclusive (referred to as direction B) as having negligible part in effecting an eastward component. The last two columns of Table 4 tabulate the respective numbers of GEK fixes made during winds from directions B and A, the remaining compass points.

The corrected data of Cruises T331, T358b, G5618, G5706, and G5707 are intended to demonstrate the existence of horizontal waves. Cruise G5618, consisting of five GEK and one hydrographic transects, was executed with short rest intervals. The hours, dates, traverse direction of each transect, and the corrected GEK values are tabulated in Table 5. The continuity of data is assured by Cruises G5706-7 when GEK measurements were made consecutively for 28 hours each cruise at two locations: Station A at 25° 44.7′N and 79° 52.5′W and Station B at the same latitude but at 79° 45.9′W. These positions straddle the climatological current axis. Position determinations were by land sighting, dead reckoning, and shipboard radar and may be ½ mi off in poor weather. The data of Cruises G5706-7 are tabulated in Table 6 and plotted in Figures 2 and 3; in Figure 2, right half, the data have been extended by inclusion of data taken when the vessel proceeded to Cat Cay from Station B and during her subsequent return to Miami ten hours later; the words 'before' and 'after' mean before and after wind drift and windage corrections. The salinity section of G5618 and GEK transects of T331 and T358b are plotted respectively in Figures 4 and 5.

Discussion—GEK measurement of 'permanent' current is thought to be unaffected by tidal stream as the latter is considered constant with depth except in the friction layer. However, *Hela* and *Wagner* [1954] detected tidal influence, supported by present data in Figure 1, in the north component of GEK current. Since the resistivity of the channel bed is high and the width of the tide wave is narrow, it appears that the friction layer is relatively thick, a conclusion at variance with that of *Reid* [1958]. The question of tidal effect on the transverse component was studied by *Chew* and *Wagner* [1954]. They assumed that the semidiurnal tide is a long progressive wave and found that for a tidal amplitude of 40 cm, the transverse tidal stream exceeds 10 cm/s only when the depth is less than 160 m. This value is considerably less than many GEK values in deeper water.

One would also expect a direct phase relationship between the observed transverse component and the transverse tidal stream induced by shelving shores, if the tidal stream were to have a direct influence. Since the tide wave propagates southward, counterclockwise and clockwise rotary currents are expected in the western and eastern half of the Strait, respectively. No such pattern is apparent in Figure 1. This result implies that whatever transverse tide currents may exist are masked by stronger transverse currents whose origin is not directly tidal.

The higher frequency of eastward component over the westward one is shown clearly in Table 2, based on uncorrected data. That the result is independent of local winds is demonstrated in Table 4: 190 GEK fixes made when the winds would have favored a westward component compared to 119 fixes when the winds would have favored an eastward current. The same higher frequency feature is shown in Table 3 based on corrected data.

East of 79.9° W, greater frequency and greater magnitude of eastward component coincide, implying a net eastward surface transport. Similarly, a net westward surface transport is indicated west of 79.9°. In turn, convergences at both the western and eastern walls of the Strait are suggested. These aperiodic motions appear to be consistent with the vorticity equation.

Under reasonable restrictions and the assumption that $\partial v/\partial y = 0$, the change of the vertical component of absolute vorticity of a water parcel is

$$\frac{D}{Dt}(f + \zeta) = -(f + \zeta)\frac{\partial u}{\partial x} + \frac{\partial F}{\partial x} \qquad (13)$$

where $(f + \zeta)$ is the absolute vorticity, always positive. F is the boundary friction of the walls of the Strait, and $\partial u/\partial x$ is the east-west component of horizontal divergence. Near the western wall, $(\partial F/\partial x)$ is positive, $(\partial u/\partial x)$ is negative; hence the parcel gains absolute vorticity with time and so tends to increase its relative cyclonic shear. Near the eastern wall, both $(\partial F/\partial x)$ and $(\partial u/\partial x)$ are negative, hence the parcel tends to conserve its absolute vorticity. Away from the walls, $(\partial F/\partial x)$ in negligible, while mass continuity requires a positive $(\partial u/\partial x)$, hence parcels in the free stream tend

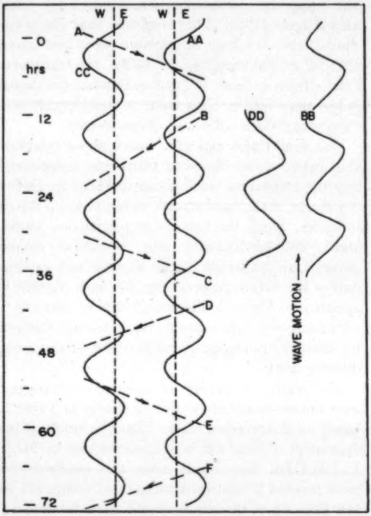

FIG. 6 – Postulated horizontal wave motion in the Straits

to gain anticyclonic vorticity. This vorticity change pattern is in accord with observations showing an intense cyclonic shear off Miami, an average current axis some $\frac{1}{3}$ the distance from Miami to Cat Cay, and a broad region of anticyclonic shear east of the axis. *Stommel* [1953], on the basis of conservation of absolute vorticity, had suggested vertical shrinking of the water column as the cause for the broad region of anticyclonic shear.

The net surface transverse flow requires a return flow at greater depths; for this circumstance, LSS find, the GEK would give actual speed. This relationship is used as a further check on the validity of the present data. From Tables 2 and 3, the speed of the net transverse surface component for Positions 2 and 3 are −2 and 4 cm/s respectively; this divergence, if extending to 100-m depth, would require an upwelling of 0.07 cm/s, a magnitude pushing the upper limit of plausibility. Again, the GEK values are consistent with other considerations.

The irregular appearance of Figure 3 is due, in part, to wind difference and, in part, to the coarse wind drift and windage corrections. Nevertheless, Figures 2 and 3 strongly suggest frequent direction changes in the transverse component, though one cannot ascribe simple periodicity to them. The data of G5618 appear most readily explained if periodicity were assumed. Let the solid curve AA in Figure 6 be the assumed horizontal transverse motion at a fixed locality, drawn with a 12-lunar-hr period and with the indicated asymmetry corresponding to greater frequency and magnitude of eastward component east of 79° 55′ W long. The short dashed lines marked A, C. . . F, correspond to the transects listed in Table 5. Thus during transect C, eastward components are encountered all the way, while during F, eastward components encountered near Cat Cay became westward near Miami. If only the trend of east-west components is considered, one finds a good correspondence between observed and postulated.

For convenience, the curve AA was drawn as a sine curve and the zero reference then displaced. For the zone west of 79° 55′, zero reference is displaced eastward as in curve CC. Figure 6. When a uniform northward component is added vectorially to these transverse components, one obtains wavy streamlines as schematically illustrated by curves BB and DD for their respective zones.

The salinity section of G5618 was executed between transects A and C. There was a 5.6-hr rest between the last GEK of transect A and the first hydrographic station. The hydro-section lasted 11 hr and was followed by an 8.2-hr rest. The resulting section, Figure 4, is not typical. Comparison with a typical one [for example, *Sverdrup* and others, 1946, Fig. 184] shows that instead of the single continuous salinity maximum tapering off westward, there are two maxima in the present section. The eastern maximum is the dominant one; but, off Miami, there is a distinct secondary high. Since the first and last stations were occupied near a westernmost displacement in the horizontal wave (the spatial relation of this hydro-section to the phases of the postulated waves is indicated by the dashed line B in Figure 6), it is likely that the westward displacement of the eastern maximum and the appearance of the separate maximum off Miami are advected there by the horizontal wave. (Here, non-synoptic data and divergence complicated the pattern.) Further, the surface transverse motion is seen extending to 150 or 200 m.

A return flow at greater depths as in internal waves appears likely for two reasons. First, the magnitude of the transverse component seems sufficiently large to expect the potential generated by the surface motion to be nullified completely by an opposite potential generated by reverse flow in lower layers. The average and maximum magnitudes (Tables 5 and 6) agree very closely with those of Pillsbury, reported by *Stommel* [1955]. Second, if return flow is non-existent, the motion would require a sea surface fluctuation whose amplitude may be estimated. The transverse component u may be taken as

$$u = 20(x/19 \times 10^5) \cos(2\pi t/T) \qquad (14)$$

obtained by assuming a linear decrease from 20 cm/s at station A, to 0 off Miami, 19 km away. Substituting (14)

$$\partial s/\partial t = -h(\partial u/\partial x) \qquad (15)$$

where s is the sea surface, setting h as 150 m, and integrating over a quarter period (3 hr), one obtains an amplitude of over 30 ft, twenty times that observed. It would appear that the fact of return flow may be confirmed or denied readily by bathythermograph lowerings near Stations A and B. Unfortunately, the situation is complicated by transport changes, wind mixing, and position uncertainty in a region of strong horizontal thermal gradient.

The salinity pattern of Figure 4 strongly resembles one reported by *Parr* [1937, Fig. 13] for hour 12. Parr suggested transverse extrusion for the western salinity maximum with a 12-lunar-hr period. *Stommel* [1955] reporting on surface current measured by Pillsbury, noted current direction of the "same sign tend to occur in blocks of 2 to 16-hour duration." Considering sampling errors and complexity of nature, it is probable that these features are actually aspects of the same phenomenon. The relation of this phenomenon to the fine structure and meandering behavior of the Gulf Stream System [*von Arx* and others, 1955; *O'Hare* and others, 1954; and others] is very suggestive. But further study is indicated, since more than speculation is desired.

If the Florida Straits is considered as a channel connecting two large basins, *Wertheim* [1953], the Atlantic with its semi-diurnal tides and the Gulf of Mexico with its predominant diurnal tides, then physical forces are present to impress on the Florida Current constituent periods of 12 and 24 lunar hr. The different apparent periods in Figures 2 and 3 may correspond to changing amplitude and phase relationships in the two primary periods while the northward wave motion assumed in Figure 6 could have been initiated by tidal phenomena transmitted through the Old Bahama Channel. It may be significant that the free periods of internal waves in a two-layer system on a rotating Earth for the average conditions of the Straits off Miami and Key West are 12 and 19 hr.

Conclusion—The pattern of transverse component of the GEK current reflects the pattern of the actual surface transverse component of the Florida Current. Two constituents of the transverse component are established. Both involve a return flow at greater depths, and both are unrelated to direct tidal stream and local winds. One constituent is an integral part of internal seiches with its surface current reversing direction every 8 to 16 hours. The other is a diverging surface transverse flow in the free stream apparently caused by boundary friction.

Computation of the Ocean-Wave Forces on Inclined Cylinders*

L. E. BORGMAN

Abstract—After a review of the assumptions in the wave force formula for vertical cylinders proposed by *Morison, O'Brien, Johnson,* and *Schaaf* [1950], a formula embodying the same assumptions is advanced for the determination of the wave forces on an arbitrarily oriented cylinder. Essentially the x components of the water-particle velocity and acceleration in the vertical-cylinder formula are each replaced by the component of the vector (velocity or acceleration) which is perpendicular to the cylinder axis and in the plane common to the vector and the cylinder axis. The resulting equation is expressed in vector and matrix notation. A concise computational procedure which allows the use of either variable or constant coefficients is outlined and a sample calculation is provided.

Introduction—Formulas for the ocean-wave forces on vertical cylinders have been investigated considerably during the past several years. The most widely used formula growing out of this effort is that proposed by *Morison, O'Brien, Johnson,* and *Schaaf* [1950] (hereafter referred to as MOJS). This equation has been extensively applied both in the interpretation of experimental data and in the prediction of wave forces. Unfortunately, no corresponding formula has been developed and tested for the analysis of wave forces on inclined cylinders. In the following discussion, we will generalize the MOJS formula so that it will apply to cylinders arbitrarily inclined in three dimensions and will then develop mathematical techniques facilitating computation with this generalization.

Formula for wave forces on vertical piling—The MOJS formula (ignoring end effects) is

$$f_x = C_D \frac{w}{2g} D v_x |v_x| + C_m \frac{w}{g} \frac{\pi D^2}{4} a_x \tag{1}$$

where the subscript x refers to the component in the direction of wave propagation, f is the force per unit length of cylinder, C_D and C_m are the drag and inertial coefficients respectively, w is the specific weight of the fluid, g is the acceleration due to gravity, D is the cylinder diameter, and v and a are the water particle velocities and accelerations respectively. The symbol $|v_x|$ denotes the positive numerical value of v_x. We note that the formula tacitly assumes that the force on a vertical pile is a function solely of the horizontal components of the water-particle velocity and acceleration. The actual velocity and acceleration vectors are not necessarily horizontal and indeed achieve this condition only at the wave crest and at the trough. In essence, as illustrated in Figure 1, the method assumes that the total acceleration and velocity vectors represented in the figures by the vector $\mathbf{p}$ can be resolved into a horizontal component which is perpendicular to the cylinder axis and a vertical component which is parallel to the cylinder. The force on the pile is considered to be a function solely of the normal component.

Formula for the forces on inclined cylinders—If (1) is physically correct, the above comments would rather strongly suggest that the force on a cylinder which is randomly oriented could be computed in an analogous way using the component of the velocity and acceleration perpendicular to the cylinder axis and ignoring the component parallel to the cylinder axis. This hypothesis has been partially verified in a series of experiments conducted at the David Taylor Model Basin [*Pode*, 1950] to determine the hydrodynamic forces on an inclined cable under steady flow conditions. These studies showed that the force, which acts in a direction perpendicular to the cable, could be represented by

$$f = C_D \frac{w}{2g} D v^2 \sin^2 \phi \tag{2}$$

where ϕ is the angle between the velocity vector and the cable axis. But since $v \sin \phi$ is equal to the component of the velocity normal to the cylinder axis, the formula may be rewritten as

$$f = C_D \frac{w}{2g} D v_n^2 \tag{3}$$

During the course of the work at the Model Basin the magnitude of the force on the cable caused by the flow component parallel to the cable axis was

---

* Publication No. 20, Technical Services Division, Shell Oil Company, Houston, Texas.

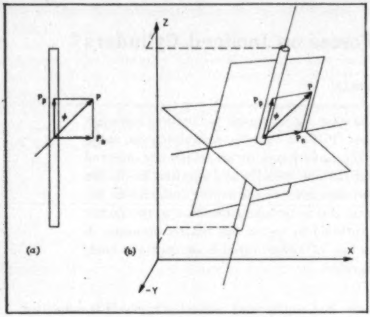

FIG. 1 – Geometrical aspects of (a) vertical and (b) randomly inclined cylinders

also determined. The axial force was found to have a magnitude less than two per cent of the perpendicular force, which indicated, as previously supposed, that the parallel flow components could be ignored in calculations. *Watson* [1953] independently checked the use of the $\sin^2 \phi$ term for the force expression in a series of towing tests on submerged wooden dowels. He obtained excellent agreement with the formula used in the Model Basin studies.

Although the experiments cited were performed only for the drag force in steady flow, it is very likely that the axial forces are also negligible in unsteady flow on smooth piling. If we make this assumption, the MOJS formula can be rewritten for the case of a randomly oriented cylinder as

$$\mathbf{f} = C_D \frac{w}{2g} D \mathbf{v}_n v_n + C_M \frac{w}{g} \frac{\pi D^2}{4} \mathbf{a}_n \tag{4}$$

In (4) $\mathbf{v}_n$ is defined as $v_n \mathbf{Q}$, where $\mathbf{Q}$ is a unit vector (see Fig. 1 where $\mathbf{p}_n$ may be interpreted as $\mathbf{v}_n$) which is both in the plane perpendicular to the cylinder axis and in the plane common to the velocity vector $\mathbf{v}$ and the cylinder axis, and which is chosen so that $\mathbf{Q} \cdot \mathbf{v} \geqq 0$. The vector $\mathbf{a}_n$ is defined in an analogous way.

Computation of $\mathbf{v}_n$ *,* v_n *, and* $\mathbf{a}_n$—In order to use (4), we need a convenient computational method for determining $\mathbf{v}_n$, v_n , and $\mathbf{a}_n$. Methods using vector and matrix notation are available for this purpose. We define $\mathbf{c}$ as a unit vector directed either up or down the cylinder axis; $\mathbf{v}$ and $\mathbf{a}$ are the water-particle velocity and acceleration respectively. In the following formulas we denote $\mathbf{v}$, $\mathbf{a}$, and $\mathbf{c}$ both in vector and matrix notation as

$$\left.\begin{array}{lll} \mathbf{v} = v_x\mathbf{i} + v_y\mathbf{j} + v_z\mathbf{k}, & \text{or} & (v) = (v_x , v_y , v_z) \\ \mathbf{a} = a_x\mathbf{i} + a_y\mathbf{j} + a_z\mathbf{k}, & \text{or} & (a) = (a_x , a_y , a_z) \\ \mathbf{c} = c_x\mathbf{i} + c_y\mathbf{j} + c_z\mathbf{k} & & \end{array}\right\} \tag{5}$$

where **i**, **j**, and **k**, are unit vectors parallel to the x, y, and z axes respectively.

Representation by vector algebra—By elementary vector algebra and the relation $c_x^2 + c_y^2 + c_z^2 = 1$, for direction cosines,

$$\begin{aligned} \mathbf{v}_n &= \mathbf{c} \times (\mathbf{v} \times \mathbf{c}) \\ &= [v_x - c_x(c_xv_x + c_yv_y + c_zv_z)]\mathbf{i} \\ &\qquad + [v_y - c_y(c_xv_x + c_yv_y + c_zv_z)]\mathbf{j} \\ &\qquad + [v_z - c_z(c_xv_x + c_yv_y + c_zv_z)]\mathbf{k} \end{aligned} \tag{6}$$

$$v_n = \{v_x^2 + v_y^2 + v_z^2 - (c_xv_x + c_yv_y + c_zv_z)^2\}^{\frac{1}{2}} \tag{7}$$

$$\begin{aligned} \mathbf{a}_n &= [a_x - c_x(c_xa_x + c_ya_y + c_za_z)]\mathbf{i} \\ &\qquad + [a_y - c_y(c_xa_x + c_ya_y + c_za_z)]\mathbf{j} \\ &\qquad + [a_z - c_z(c_xa_x + c_ya_y + c_za_z)]\mathbf{k} \end{aligned} \tag{8}$$

Representation by matrices—The representations by vectors, while leading to an explicit algebraic equation for $\mathbf{a}_n$, $\mathbf{v}_n$, and v_n , are not very convenient for computation and are useful mainly as suggesting a formulation of the problem in terms of matrices. This development is suggested by the relationship

$$\mathbf{p} \times \mathbf{c} = (p_x , p_y , p_z) \begin{Bmatrix} 0 & -c_z & c_y \\ c_z & 0 & -c_x \\ -c_y & c_x & 0 \end{Bmatrix} \tag{9}$$

where the standard 'row by column' multiplication of the matrices [*Birkhoff* and *MacLane*, 1953, p. 209 ff] is indicated. Then

$$\begin{aligned} \mathbf{c} \times (\mathbf{p} \times \mathbf{c}) &= -(\mathbf{p} \times \mathbf{c}) \times \mathbf{c} \\ &= -(p_x , p_y , p_z) \cdot \\ &\qquad \begin{Bmatrix} 0 & -c_z & c_y \\ c_z & 0 & -c_x \\ -c_y & c_x & 0 \end{Bmatrix} \begin{Bmatrix} 0 & -c_z & c_y \\ c_z & 0 & -c_x \\ -c_y & c_x & 0 \end{Bmatrix} \\ &= (p_x , p_y , p_z) \cdot \begin{Bmatrix} 1 - c_x^2 & -c_xc_y & -c_xc_z \\ -c_xc_y & 1 - c_y^2 & -c_yc_z \\ -c_xc_z & -c_yc_z & 1 - c_z^2 \end{Bmatrix} \end{aligned} \tag{10}$$

If (C) is the 3×3 matrix

$$(C) = \begin{Bmatrix} 1 - c_x^2 & -c_xc_y & -c_xc_z \\ -c_xc_y & 1 - c_y^2 & -c_yc_z \\ -c_xc_z & -c_yc_z & 1 - c_z^2 \end{Bmatrix}$$

Then the formula for $\mathbf{v}_n$, v_n , and $\mathbf{a}_n$ in matrix form becomes

$$(v_n) = (v_{nx} , v_{ny} , v_{nz}) = (v)(C) \tag{11}$$

$$v_n = \{(v_n)(v_n)^T\}^{\frac{1}{2}} \tag{12}$$

$$(a_n) = (a_{nx} , a_{ny} , a_{nz}) = (a)(C) \tag{13}$$

where $(v_n)^T$ denotes the transpose of (v_n).

Total combined force on a cylinder—In normal practice, several points along the axis of the cylinder are selected and the force per foot is computed at each point. The total force on the cylinder can then be determined by numerical integration along the cylinder axis. This whole procedure can be concisely stated in terms of matrix algebra.

As a convention to avoid writing unnecessary zeros, we formally define square brackets to mean

$$\begin{bmatrix} b_1 \\ b_2 \\ b_3 \\ \cdot \\ \cdot \\ \cdot \\ b_m \end{bmatrix} = \begin{Bmatrix} b_1 & 0 & 0 & \cdots & 0 \\ 0 & b_2 & 0 & \cdots & 0 \\ 0 & 0 & b_3 & \cdots & 0 \\ \cdot & \cdot & \cdot & & \cdot \\ \cdot & \cdot & \cdot & & \cdot \\ \cdot & \cdot & \cdot & & \cdot \\ 0 & 0 & 0 & \cdots & b_m \end{Bmatrix} \tag{14}$$

Multiplication by a column of elements in square brackets proceeds exactly as though the corresponding diagonal matrix were being used.

If m points along the cylinder axis are selected for computation, the formula is

$$\begin{Bmatrix} f_{x1} & f_{y1} & f_{z1} \\ f_{x2} & f_{y2} & f_{z2} \\ \cdot & \cdot & \cdot \\ \cdot & \cdot & \cdot \\ \cdot & \cdot & \cdot \\ f_{xm} & f_{ym} & f_{zm} \end{Bmatrix} = C_D \frac{w}{2g} D \begin{bmatrix} |v_{n1}| \\ |v_{n2}| \\ \cdot \\ \cdot \\ \cdot \\ |v_{nm}| \end{bmatrix} \cdot \begin{Bmatrix} v_{x1} & v_{y1} & v_{z1} \\ v_{x2} & v_{y2} & v_{z2} \\ \cdot & \cdot & \cdot \\ \cdot & \cdot & \cdot \\ \cdot & \cdot & \cdot \\ v_{xm} & v_{ym} & v_{zm} \end{Bmatrix} \begin{Bmatrix} 1 - c_x^2 & -c_xc_y & -c_xc_z \\ -c_xc_y & 1 - c_y^2 & -c_yc_z \\ -c_xc_z & -c_yc_z & 1 - c_z^2 \end{Bmatrix}$$
$$+ C_M \frac{w}{g} \frac{\pi D^2}{4} \begin{Bmatrix} a_{x1} & a_{y1} & a_{z1} \\ a_{x2} & a_{y2} & a_{z2} \\ \cdot & \cdot & \cdot \\ \cdot & \cdot & \cdot \\ \cdot & \cdot & \cdot \\ a_{xm} & a_{ym} & a_{zm} \end{Bmatrix} \cdot \begin{Bmatrix} 1 - c_x^2 & -c_xc_y & -c_xc_z \\ -c_xc_y & 1 - c_y^2 & -c_yc_z \\ -c_xc_z & -c_yc_z & 1 - c_z^2 \end{Bmatrix} \tag{15}$$

In the above formula, the kth row in each matrix represents the variable at the kth point along the cylinder axis. That is, (v_{xk}, v_{yk}, v_{zk}) and (a_{xk}, a_{yk}, a_{zk}) respectively are the components of the water-particle velocity and acceleration vectors at the kth point. Similarly (f_{xk}, f_{yk}, f_{zk}) are the force per unit length in the x, y, and z directions, respectively, at the kth point. The matrix $[|v_{ni}|]$ is a function of the matrix product, $(v_i)(C)$. In particular, since

$$\begin{Bmatrix} v_{nx1} & v_{ny1} & v_{nz1} \\ v_{nx2} & v_{ny2} & v_{nz2} \\ \cdot & \cdot & \cdot \\ \cdot & \cdot & \cdot \\ \cdot & \cdot & \cdot \\ v_{nxm} & v_{nym} & v_{nzm} \end{Bmatrix} = \begin{Bmatrix} v_{x1} & v_{y1} & v_{z1} \\ v_{x2} & v_{y2} & v_{z2} \\ \cdot & \cdot & \cdot \\ \cdot & \cdot & \cdot \\ \cdot & \cdot & \cdot \\ v_{xm} & v_{ym} & v_{zm} \end{Bmatrix} \cdot \begin{Bmatrix} 1 - c_x^2 & -c_xc_y & -c_xc_z \\ -c_xc_y & 1 - c_y^2 & -c_yc_z \\ -c_xc_z & -c_yc_z & 1 - c_z^2 \end{Bmatrix} \tag{16}$$

the ith element of $[|v_{ni}|]$ is

$$|v_{ni}| = \sqrt{v_{nxi}^2 + v_{nyi}^2 + v_{nzi}^2} \tag{17}$$

The total force may be determined by numerical integration down the columns of (f_i) in (15).

Variable coefficients—One additional generalization of (15) is possible. Some of the recent experiments seem to indicate that C_D and C_M are variables and might, in some manner, be functions of Reynolds number, Iverson's modulus, or other quantities. The formula can be easily modified to include variable coefficients as

$$\begin{Bmatrix} f_{x1} & f_{y1} & f_{z1} \\ f_{x2} & f_{y2} & f_{z2} \\ \cdot & \cdot & \cdot \\ \cdot & \cdot & \cdot \\ \cdot & \cdot & \cdot \\ f_{xm} & f_{ym} & f_{zm} \end{Bmatrix} = \frac{w}{2g} \begin{bmatrix} C_{D1} \\ C_{D2} \\ \cdot \\ \cdot \\ \cdot \\ C_{Dm} \end{bmatrix} \begin{bmatrix} D\,|v_{n1}| \\ D\,|v_{n2}| \\ \cdot \\ \cdot \\ \cdot \\ D\,|v_{nm}| \end{bmatrix} \cdot \begin{Bmatrix} v_{x1} & v_{y1} & v_{z1} \\ v_{x2} & v_{y2} & v_{z2} \\ \cdot & \cdot & \cdot \\ \cdot & \cdot & \cdot \\ \cdot & \cdot & \cdot \\ v_{xm} & v_{ym} & v_{zm} \end{Bmatrix} \begin{Bmatrix} 1 - c_x^2 & -c_xc_y & -c_xc_z \\ -c_xc_y & 1 - c_y^2 & -c_yc_z \\ -c_xc_z & -c_yc_z & 1 - c_z^2 \end{Bmatrix}$$
$$+ \frac{w}{g} \frac{\pi D^2}{4} \begin{bmatrix} C_{M1} \\ C_{M2} \\ \cdot \\ \cdot \\ \cdot \\ C_{Mm} \end{bmatrix} \begin{Bmatrix} a_{x1} & a_{y1} & a_{z1} \\ a_{x2} & a_{y2} & a_{z2} \\ \cdot & \cdot & \cdot \\ \cdot & \cdot & \cdot \\ \cdot & \cdot & \cdot \\ a_{xm} & a_{ym} & a_{zm} \end{Bmatrix} \cdot \begin{Bmatrix} 1 - c_x^2 & -c_xc_y & -c_xc_z \\ -c_xc_y & 1 - c_y^2 & -c_yc_z \\ -c_xc_z & -c_yc_z & 1 - c_z^2 \end{Bmatrix} \tag{18}$$

After computing $(v_i)(C)$, $|v_{ni}|$ is computed by (17) and multiplied by D to obtain the ith element in $[D\,|v_{ni}|]$. Since the Reynolds number for sea water is approximately $10^5 D\,|v_n|$, the elements in $[D\,|v_{ni}|]$ essentially give the Reynolds numbers along the pile. $[C_{Di}]$ can now be determined by whatever variable curves have been previously selected. The computation of the inertial forces proceeds in an analogous fashion except there is no matrix corresponding to $[D \mid v_{ni} |]$; however a subsidiary matrix, $[| a_{ni} |]$, may be computed in a manner similar to (17) if it is desired to make C_M depend on the magnitude of the normal acceleration in some way.

Simplifications caused by zero columns and rows—In most computations, a two-dimensional wave theory is used to calculate **v** and **a**. In this case, one of the columns in each of the matrices (v) and (a) will consist entirely of zero elements. Alternately, one of the rows in the (C) matrix may be composed entirely of zeros for certain orientations of the cylinder. In either case, it is unnecessary to write down the column or row of zeros since they never affect the answer. If jth column in (v_i) or (a_i) is zero, the jth row in the (C) matrix by which it is to be multiplied may be crossed out. Similarly, if the jth row in (C) is zero, the jth column in (a_i) and (v_i) may be crossed out.

Sample calculation—To illustrate the foregoing, a computation will be made of the forces on a 2-ft dia cylinder, 42.5 ft long, with direction cosines $c_x = 0.551$, $c_y = 0.122$, and $c_z = 0.826$. We assume that three points along the cylinder will determine the total force with sufficient accuracy. Furthermore, we suppose that the (v_i) and (a_i) matrices are

$$(v_{xi}, v_{yi}, v_{zi}) = \begin{Bmatrix} 12.5 & 0 & 0.2 \\ 12.5 & 0 & 2.9 \\ 10.9 & 0 & 8.3 \end{Bmatrix} \text{ ft/sec}$$

$$(a_{xi}, a_{yi}, a_{zi}) = \begin{Bmatrix} 1.4 & 0 & -0.7 \\ 4.7 & 0 & -2.0 \\ 9.7 & 0 & +2.8 \end{Bmatrix} \text{ ft/sec}^2$$

The matrix (C) is given by

$$(C) = \begin{Bmatrix} 0.696 & -0.067 & -0.455 \\ -0.067 & 0.985 & -0.101 \\ -0.455 & -0.101 & 0.318 \end{Bmatrix}$$

To illustrate the procedure for both variable and fixed coefficients, we will use the steady state C_D as a function of the Reynolds number [*Rouse*, 1950, p. 124] and a fixed C_M value of 1.5. Then the relevant parts of (15) and (18) give the formula as

$$\begin{Bmatrix} f_{x1} & f_{y1} & f_{z1} \\ f_{x2} & f_{y2} & f_{z2} \\ f_{x3} & f_{y3} & f_{z3} \end{Bmatrix} = \frac{w}{2g} [C_{Di}][D|v_{ni}|] \begin{Bmatrix} 12.5 & 0.2 \\ 12.5 & 2.9 \\ 10.9 & 8.3 \end{Bmatrix}$$

$$\cdot \begin{Bmatrix} 0.696 & -0.067 & -0.455 \\ -0.455 & -0.101 & 0.318 \end{Bmatrix} + C_M \frac{w}{g} \frac{\pi D^2}{4}$$

$$\cdot \begin{Bmatrix} 1.4 & -0.7 \\ 4.7 & -2.0 \\ 9.7 & +2.8 \end{Bmatrix} \begin{Bmatrix} 0.696 & -0.067 & -0.455 \\ -0.455 & -0.101 & 0.318 \end{Bmatrix}$$

$$= 0.993 \begin{bmatrix} 0.36 \\ 0.36 \\ 0.33 \end{bmatrix} \begin{bmatrix} 20.6 \\ 17.6 \\ 9.5 \end{bmatrix} \begin{Bmatrix} 8.61 & -0.86 & -5.62 \\ 7.38 & -1.13 & -4.77 \\ 3.81 & -1.57 & -2.32 \end{Bmatrix}$$

$$+ 9.37 \begin{Bmatrix} 1.29 & -0.02 & -0.86 \\ 4.18 & -0.11 & -2.77 \\ 5.48 & -0.93 & -3.52 \end{Bmatrix}$$

$$= \begin{Bmatrix} 63.4 & -6.3 & -41.4 \\ 46.4 & -7.1 & -30.0 \\ 11.8 & -4.9 & -\ 7.2 \end{Bmatrix} + \begin{Bmatrix} 12.1 & -0.2 & -\ 8.1 \\ 39.2 & -1.0 & -26.0 \\ 51.3 & -8.7 & -33.0 \end{Bmatrix}$$

$$= \begin{Bmatrix} 75.5 & -\ 6.5 & -49.5 \\ 85.6 & -\ 8.1 & -56.0 \\ 63.1 & -13.6 & -40.2 \end{Bmatrix} \text{ lb/ft}$$

The total force on the cylinder is then, by trapezoidal rule integration,

$$(F_x, F_y, F_z) = (3292, -386, -2143) \text{ lb.}$$

Concluding remarks—Although the formula presented is a speculative extension of the MOJS formula to three dimensions and will require experimental verification before it can be used with confidence, the methods of computation shown should be useful in any three-dimensional wave-force formula. An analogous generalization can easily be prepared, for instance, for the formula outlined by *Crooke* [1955] which uses Iverson's modulus. Indeed the general methods presented should be useful in a wide variety of three-dimensional fluid-flow problems, both for steady-state conditions and for continually varying systems.

Acknowledgment—I wish to express my appreciation to the Shell Oil Co. for its support in the investigations and for permission to publish the paper. The suggestions made by J. E. Chappelear and J. E. Lacy, who reviewed the paper, are also gratefully acknowledged.

The Equilibrium Beach

WILLIAM F. TANNER

Abstract—The equilibrium beach has curvature and sand-prism characteristics adjusted to each other so delicately that the potential littoral motion provides precisely the energy needed to transport the detritus supplied at the up-current end. The time element in this balance is long-term rather than instantaneous. A beach which performs in any other way is not in equilibrium. The maintenance of certain beaches in equilibrium form is of great economic or political importance. The most pressing case of inequilibrium is that of the rapidly retrograding beach. In many instances the beach can be restored to an equilibrium condition by decreasing the actual littoral drift or increasing the available supply of sand.

The concept of the graded stream is basic to an understanding of river behavior. *Mackin* [1948] has summarized the idea clearly, with several excellent examples. *Leopold* and *Miller* [1956] have detailed certain aspects of the concept. A simple definition, modified from Mackin, may be given as follows:

The graded stream has slope and channel characteristics adjusted to each other so delicately that the available discharge provides precisely the energy needed to transport the bed load supplied from the drainage basin. The time element in this balance is long-term rather than instantaneous. The balance is so arranged that an alteration in any one of the controlling factors will shift the equilibrium enough to absorb the effect of the change. A stream which performs in any other way is not graded. The changes which a graded stream may make, in order to maintain such a balance, include alteration of: (1) gradient, (2) tortuosity, (3) hydraulic radius, and (4) channel roughness. (But these four are not to be thought of as equal in effect or likelihood.) The same idea is used by engineers who refer to 'poised' or 'regime' streams [*Blench*, 1957, pp. 2–3].

A similar concept can be applied, with good advantage, to beaches and other types of coast line [*Schijf*, 1957]. The term 'equilibrium beach,' however, should not be considered a duplicate of the term 'equilibrium profile.' The latter is taken at right angles to the coast line, and considered in a vertical plane. The former should be taken parallel with the coast line and examined in a horizontal plane.

The analogy with the graded river can be made clearer if the river channel is said, at any given spot, to have elevation rather than gradient. When the gradient is altered, the elevation is generally changed. The beach also has a 'convergence' or 'gradient' which lies, however, in a horizontal plane. We find it difficult to visualize because we have no convenient reference plane to which it is asymptotic, such as that furnished by sea level for the river profile. There is, however, a vertical plane containing a horizontal line with which the shoreline tends to converge. This horizontal line might be called the 'ultimate shoreline.' Its orientation, and therefore the angle of convergence with the actual shoreline, may be estimated, in some instances, from the maximum fetch and the wave resultant [*Guilcher*, 1958]. The calculated angle will generally be quite small. The suggestion that the river bed be said to have elevation, that is, vertical position, leads to the observation that the beach has position in a horizontal plane. Hence its 'convergence' with the 'ultimate shoreline' can be seen in some of the curves which we observe in map view. The chief differences between the stream gradient, and the beach 'convergence' or curvature, are:

River gradient	Shore-line 'convergence' or curvature
Lies in vertical plane	Lies in horizontal plane
Has sea level as a reference plane	Has no obvious reference plane
Gradient reversals result in ponding	Local ponding does not occur

A beach can be studied in terms of the sediment introduced at one end, and removed at the other. The two quantities are not necessarily equal. Sediment may be lost by deflation inland (that is, as sand dunes), or by seaward drift across the continental shelf; in either instance, the volume of sediment introduced exceeds the volume of sediment delivered. On the other hand, additional sediment may be acquired from the land (that is, by rivers or rain-wash) or from the sea floor; for such conditions, the volume of sediment introduced is less than the volume delivered. There is also a third pair of possibilities: the coast may be retrograded (moved, horizontally, toward the land), or prograded (moved, horizontally, toward the sea), to offset an excess or deficit of sediment. It is possible, of course, to have a seventh possibility: the two volumes of sediment are equal, and there is no change in the position of the shoreline.

These seven conditions, and their various combinations, are derived from the fact that the beach, like the granular material on many river beds, is in constant motion. It is more free to move in either direction than is river bed-load, but, like the river detritus, it commonly moves eventually in a single direction. (The transporting energy is in general derived from wind-driven waves, rather than from gravity; hence the greater freedom in direction.)

River bed load lies as fill in a more-or-less U-shaped channel. Its lower surface is fixed by the shape of the maximum flood channel, its upper surface during low-water stages. The beach likewise lies on an eroded surface, cut during times of high tides and high waves. Its upper surface is shaped, most of the time, by relatively quiet waters. The lower, cut, surface exhibits, in cross section, an equilibrium profile for storm conditions. The upper, deposited, surface exhibits, in cross section, an equilibrium profile for calm conditions. The beach is the prism of moving sand which lies, at any given instant, between these two surfaces. If the quantity of sand in this prism is relatively great, seasonal and other short-term changes in transportation can be absorbed without altering the character of the beach.

The beach has 'convergence' or 'curvature' in a horizontal plane, energy in a single net direction, and a prism of sediments in transport. It has, in addition, other characteristics of an alluvial river, such as sediment surface roughness. It does not have tortuosity (in a plane at right angles to the plane containing the 'convergence') comparable with the meanders of a river. Nor does it have hydraulic radius. Instead, the beach has steepness (which varies with, among other things, sediment grain size).

The channel characteristics of a river include its tortuosity, hydraulic radius, and roughness. The prism characteristics of a beach include its steepness, thickness, and roughness.

The similarities of the two systems are considerable. Both result from directed streams of moving water. Hence the concept of an equilibrium beach may be fruitful. A definition might be offered as follows:

The equilibrium beach has curvature and sand prism characteristics adjusted to each other so delicately that the potential littoral motion provides precisely the energy needed to transport the detritus supplied at the up-current end. The time element in this balance is long-term rather than instantaneous. A beach which performs in any other way is not in equilibrium.

Under such a definition, a pocket beach does not attain an equilibrium configuration before it succeeds in filling its indentation. Likewise, a shoreline composed exclusively of bare rocks does not have an equilibrium curvature.

The problems of beach control can be evaluated in the light of the concept of the equilibrium beach. A shoreline which migrates rapidly landward does so because not enough sediment is introduced at the up-current end to absorb all the energy provided by the potential littoral drift. It is not an equilibrium shoreline. A river of similar nature scours its bed, over a long term, because it has an excess of gravitational energy. Such a river is generally considered to be, geologically, youthful, regardless of its chronologic age or its past history. In this sense, the beach is immature, or sub-mature, or rejuvenated.

The associated political, social, and economic problems may be enormous. The east coast of Florida has, today, such a shoreline. It is migrating landward because of a deficit of detritus for southward transportation. In the past, efforts have been made to correct the situation by building groynes and other similar installations. It should be obvious that there are only two ultimate solutions: decrease the net unidirectional energy, or increase the amount of sediment available. The former is, at present, unthinkable. The latter can be handled, at least temporarily, by pumping sand in from adjacent areas. Such a program is now being studied [*Bruun*, 1957]. Groynes may provide a partial solution by absorbing some of the wave energy, thus permitting a more leisurely littoral drift, and therefore increasing the amount of time spent by each sand grain in transit along a given stretch of beach.

A shoreline which migrates seaward does so because the detritus introduced at the up-current end exceeds the amount which can be delivered at the opposite end. The economic problems involved are, perhaps, not so acute as those associated with a retrograding shore.

The concept of the equilibrium shoreline suggests several possible solutions, one of which would require soil conservation measures inland from the up-current area. The reverse (soil erosion measures to control a landward migrating beach) does not seem generally attractive.

Seepage of Steady Rainfall through Soil into Drains*

DON KIRKHAM

Abstract—Theoretical formulas for the height of all points of an arch-shaped water table are derived for steady rainfall seeping into homogeneous soil drained by tubes or ditches. The soil is underlain by an impermeable layer and the drains are taken to be equally spaced and equally deep. The solution is based on exact mathematical procedures, but utilizes a physical assumption that the height of the water table as measured from a reference plane passing through the lowest points of the water table is small compared to the depth of the impermeable layer. For tube drains running half full and when the impermeable layer is at great depth, the theoretical height H of the water table midway between drain tubes takes the particularly simple form, $H = (2sR/\pi k)\ln(2s/\pi r)$ where H is height above the reference plane, $2r$ is the diameter of the drain tube, $2s$ is the spacing between drain tubes, R is the rainfall rate, and k the hydraulic conductivity. Flow nets for tube and ditch drainage are presented; a table for making practical computations has been prepared. The theory is compared with field data of Kirkham and De Zeeuw; good agreement was obtained. Finally, the interesting point is brought out that the Dupuit-Forchheimer (DF) theory emerges from the general theory for the special case of very large ratio of drain spacing to height of water saturated soil and for an essentially flat water table. Thus the analysis presents a rational foundation for DF theory which has heretofore been lacking.

Statement of problem—In Figure 1a, equally spaced ditches in soil remove ground water at a steady rate equal to that of a steady rain. Evaporation is negligible and an impermeable layer prevents deep seepage. The ditches are narrow and are assumed to have water in them to the level E where the arch-shaped water table EDE intercepts them. A surface of seepage at E will be very small and is neglected. The water table, as is generally true, has small curvature; also, the distance CD is small compared to the depth CB.

It is a purpose of this paper to obtain, for Figure 1a, analytic expressions for the stream and potential functions, and hence flow nets, for the water seeping into the drains; also, to obtain an analytical expression relating the height of the water table, at all points on its profile, to the parameters, depth and spacing of ditches, depth of the impermeable layer, rate of rainfall, and hydraulic conductivity of the soil. It is a further purpose to obtain an analytical expression for the rate of fall of the water table midway between drains at the instant that the rainfall ceases. Finally, it is our purpose to obtain all the analytical solutions mentioned above, when the rain seeping into the soil, instead of being removed by ditches as in Figure 1a, is removed by other types of 'sinks,' including tube (tile) drains. For the moment we shall consider further the ditch case of Figure 1a

Physical approximations—We could conceivably solve the problem of Figure 1a exactly, by pursuing a hodograph procedure of Van Deemter discussed by *Van Schilfgaarde* and others [1956, pp. 681–695], but the analysis would be extremely complex. We accordingly seek approximate solutions based on certain simplifying physical approximations. Our mathematical analysis will be exact. The basic physical approximation is due to *Hooghoudt* [1940, pp. 555–589, esp. p. 585]. It is: the loss of hydraulic head in the arched region *EDECE* is negligible compared to the loss of head for the remainder of the flow region. Physically this means that we can replace the soil in the region *EDECE* by coarse gravel of essentially infinite conductivity, provided that we simultaneously introduce frictionless membranes of zero thickness along the streamline segments (see Fig. 1b, *LK*, *JI*, *HG*, and *DC*). Without such membranes the water in the gravel would spread out because of gravitation, and the arched form of the water table (and in particular the height *CD* we seek) could not be conceived to exist. An infinite number of membranes are needed; otherwise the arc of the water table would not be continuous.

If there is to be no loss of head in the 'gravel,' then the membranes there need not be located along the streamlines. The membranes could just as well extend vertically downward from points *LJH* in Figure 1b to the line *EC*. In this event, the streamlines would all be equally spaced along

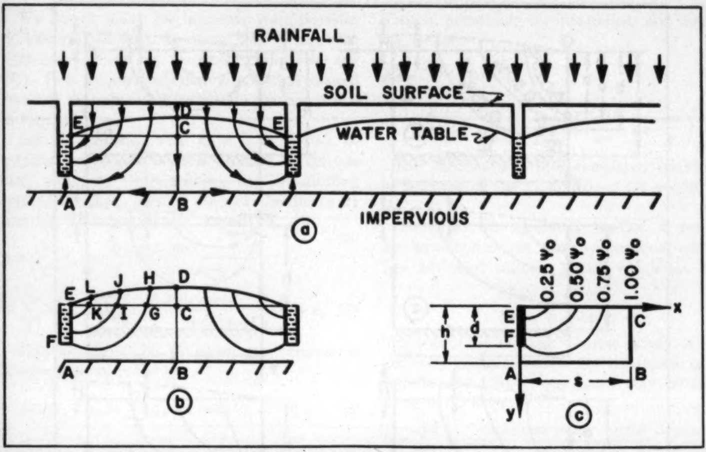

FIG. 1 – (a) Seepage of steady rainfall through soil into equally spaced ditch drains; (b) typical drainage section (c) approximate conditions for theoretical analysis; streamlines are not computed but schematic

the line *EC*, as shown in Figure 1c. We shall consider them to be so spaced. Our analysis is simplified thereby.

Our problem then can be reduced to that indicated in Figure 1c, where we let *d* be the depth of the ditch, referred to the plane *EC*; *h* the distance from *EC* to the impermeable layer and *s* the semispacing of the ditches. The ditches are initially to be taken of zero width (slits); later their finite width will be taken into account. In Figure 1c we also let the symbol ψ_0 denote the quantity of water reaching a ditch from one side per unit time per unit length of ditch. Therefore, the extreme streamline *CBAF*, entering the soil midway between ditches and leaving the soil at the bottom point *F* of the ditch, may be labelled 1.0 ψ_0; and the three other streamlines shown in Figures 1a and 1b are accordingly to be labelled 0.25 ψ_0, 0.50 ψ_0, and 0.75 ψ_0. The point *E* is a zero streamline.

If *R* is the rate of rainfall (say cubic inches per square inch of soil surface per hour, that is, inches per hour), then ψ_0 is related to *R* and the semispacing *s* by

$$\psi_0 = Rs \qquad (1)$$

Analysis

We shall determine the height *CD* of Figure 1a by first obtaining an analytical expression for the stream function ψ valid at all points in the assumed flow medium *ABCEFA* of Figure 1c, and then by determining from ψ a corresponding hydraulic head (potential) function. The latter will yield for the point *C* in Figure 1c the desired height *CD* of Figures 1a and 1b. In obtaining ψ we remember that ψ is sought not only for the ditch case of Figure 1 but for a number of other types of drainage outlets (sinks). Therefore we consider a more general problem than that of Figure 1c, a problem which will include Figure 1c as a special case. The more general problem is indicated in Figure 2a, where the sink is of vertical length $(b - a)$, with b and a as shown. Figure 2a goes over to Figure 2b by taking $a = 0$ and $b = d$. Likewise, as will later be brought out, all the situations in Figure 2 are special cases of Figure 2a.

To obtain ψ for Figure 2a, we make a further physical assumption: that the amount of water seeping into unit vertical height of slit per unit time is constant over the height of the slit. In practice this assumption would be difficult to realize because the slit would be a surface over which the hydraulic head would vary in an unrealistic manner. But the assumption does have a practical implication. A surface surrounding the slit as in Figure 2b must theoretically be a surface of equal hydraulic head. Therefore this sur-

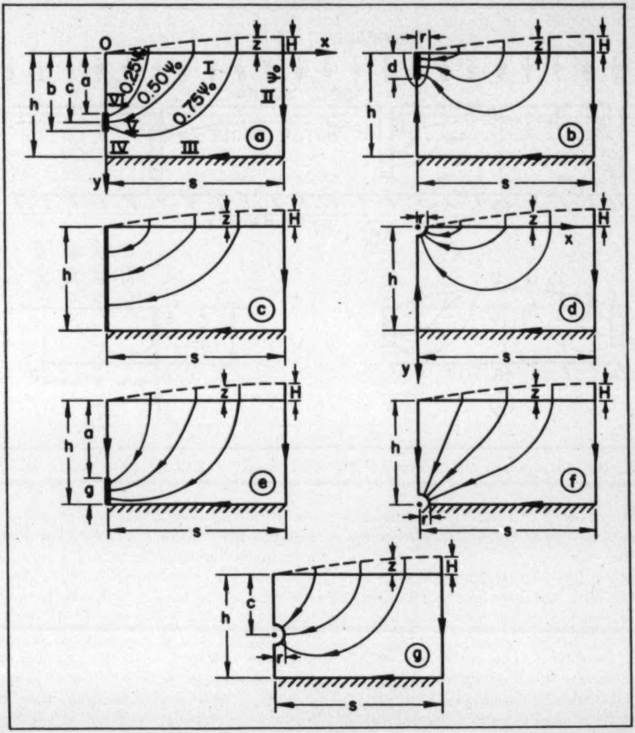

FIG. 2 – Semi-sections of seepage regions; regions are as in Fig. 1c, except that various types of sinks are included

face can be identified with an actual drain running full, as in practice. The drain must be running full, otherwise surfaces of seepage will exist over the surface and it cannot be a surface of equal hydraulic head.

Development of stream and potential functions—We have let ψ denote the stream function. We now further let ϕ be the hydraulic head and Φ a velocity potential related to ϕ by

$$\Phi = k\phi \tag{2}$$

We shall choose Φ such that $\phi = 0$ at $y = 0$ in Figure 2a. That is, the x axis as shown will be the reference level for hydraulic head, and the distance z in Figure 2 will accordingly be given by ϕ, when ϕ is evaluated at $x = x$ and $y = 0$. The height H in Figure 2 will be given by ϕ when $x = s$ and $y = 0$.

The functions ψ and Φ, in order to be correct, must satisfy the differential equations

$$\partial^2\psi/\partial x^2 + \partial^2\psi/\partial y^2 = 0 \tag{3}$$

$$\partial^2\Phi/\partial x^2 + \partial^2\Phi/\partial y^2 = 0 \tag{4}$$

and the boundary conditions.

The boundary conditions for ψ are:

At $y = 0$ $\Psi = (x/s)\Psi_0$ from $x = 0$ to s Cond. I
At $x = s$ $\Psi = \Psi_0$ from $y = 0$ to h Cond. II
At $y = h$ $\Psi = \Psi_0$ from $x = 0$ to s Cond. III
At $x = 0$ $\Psi = \Psi_0$ from $y = b$ to h Cond. IV
At $x = 0$ $\Psi = [(y - a)/(b - a)]\Psi_0$ from $y = a$ to b Cond. V
At $x = 0$ $\Psi = 0$ from $y = 0$ to a Cond. VI

We do not know the boundary conditions for Φ, but we can solve for them once ψ has been determined (from its boundary conditions and (3)). It is emphasized that a principal desired result is the value of $\phi = \Phi/k$ for the line $y = 0$ in Figure 2.

Let A_m and B_m, with $m = 1, 2, 3, \cdots$, be arbitrary constants, then a function ψ (as one may verify by differentiating and substituting into (3)), which satisfies (3) and Conditions II and III for any values of A_m and B_m, is

$$\psi = \sum_1^\infty A_m \sin \frac{m\pi x}{s} \frac{\sinh [m\pi(h-y)/s]}{\sinh (m\pi h/s)} + \sum_1^\infty B_m \sin \frac{m\pi(h-y)}{h} \frac{\sinh [m\pi(s-x)/h]}{\sinh (m\pi s/h)} + \psi_0 \quad (5)$$

Condition I and Eq. (5) yield, after transposing the constant ψ_0 to the left

$$(x/s)\psi_0 - \psi_0 = \sum_1^\infty A_m \sin (m\pi x/s), \quad x = 0 \text{ to } s \quad (6)$$

Therefore, consideration of the right hand side (RHS) of (6) as a Fourier sine series for the interval $x = 0$ to s yields

$$A_m = (2/s) \int_0^s [(x/s)\psi_0 - \psi] [\sin (m\pi x/s)] \, dx$$

That is

$$A_m = -2\psi_0 \pi^{-1} m^{-1} \quad (7)$$

Notice that the values of A_m are independent of the distances a, b, and h, and hence that the A_m values are the same for each case in Figure 2.

To obtain the B_m we utilize successively the remaining Conditions IV, V, and VI in (5), to find, after introducing a new variable z defined by $z = h - y$, the results

$$0 = \sum_1^\infty B_m \sin (m\pi z/h), \qquad z = 0 \text{ to } h - b$$

$$\frac{h - a - z}{b - a}\psi_0 - \psi_0 = \sum_1^\infty \sin (m\pi z/h), \qquad z = h - b \text{ to } h - a$$

$$-\psi_0 = \sum_1^\infty B_m \sin (m\pi z/h), \qquad z = h - a \text{ to } h$$

Thus, the B_m may be considered as coefficients of a Fourier sine series in the interval 0 to h, with the B_m given accordingly by

$$B_m = \frac{2}{h} \int_{h-b}^{h-a} \left[\frac{h - a - z}{b - a}\psi_0 - \psi_0 \right] \sin \frac{m\pi z}{h} \, dz + \frac{2}{h} \int_{h-a}^{h} (-\psi_0) \sin \frac{m\pi z}{h} \, dz$$

That is, performing the integrations and simplifying, we have

$$B_m = \frac{2\psi_0}{\pi} (-1)^m \cdot \left[\frac{1}{m} - \frac{h}{\pi m^2 (b - a)} \left(\sin \frac{m\pi b}{h} - \sin \frac{m\pi a}{h} \right) \right] \quad (8)$$

Our function ψ is thus completely determined by substituting the A_m and B_m of (7) and (8) into (5).

To obtain the potential function Φ from ψ, we now utilize the Cauchy-Riemann relations (see advanced calculus books) which are

$$\partial\Phi/\partial x = \partial\psi/\partial y \quad (9)$$

$$\partial\Phi/\partial y = -\partial\psi/\partial x \quad (10)$$

The sought-for function Φ must satisfy (4), (9), and (10) simultaneously. By inspection of (4), (5), (9), and (10) we see that Φ may be written down in the form

$$\Phi = \sum_1^\infty A_m \cos \frac{m\pi x}{s} \frac{\cosh [m\pi(h-y)/s]}{\sinh (m\pi h/s)} + \sum_1^\infty B_m \cos \frac{m\pi(h-y)}{h} \frac{\cosh [m\pi(s-x)/h]}{\sinh (m\pi s/h)} + C \quad (11)$$

where C is a constant to be chosen such that Φ for the lowest point on the water table will be $\Phi = k\phi = 0$. The constant C will also be associated with the finite width of an actual drainage facility, as will later be clear. One may verify by differentiation of (5) and (11) that (9) and (10) are satisfied by ψ and Φ of (5) and (11). If one did not see by inspection how to write down Φ from ψ, a method described by *Green* [1948, p. 51], involving complex variable, could be used. One may verify (by differentiation and substitution) that Φ as given by (11) satisfies (4).

Although (5) and (11) are correct, simpler forms can be obtained by trigonometric reduction. These forms are

$$\psi = \sum_1^\infty A_m \sin \frac{m\pi x}{s} \frac{\sinh [m\pi(h-y)/s]}{\sinh (m\pi h/s)} - \sum_1^\infty (-1)^m B_m \sin \frac{m\pi y}{h} \frac{\sinh [m\pi(s-x)/h]}{\sinh (m\pi s/h)} + \psi_0 \quad (12)$$

$$\Phi = \sum_1^\infty A_m \cos \frac{m\pi x}{s} \frac{\cosh [m\pi(h-y)/s]}{\sinh (m\pi h/s)} + \sum_1^\infty (-1)^m B_m \cos \frac{m\pi y}{h} \frac{\cosh [m\pi(s-x)/h]}{\sinh (m\pi x/h)} + C \quad (13)$$

RAPIDLY CONVERGENT SERIES FOR ψ AND Φ

The A_m, as given by (7), and the B_m, as given by (8), when substituted in (12) and (13), yield ψ and Φ for the case of Figure 2a. The results for ψ and Φ are rapidly converging infinite series, except, unfortunately, for values of x and y near the sinks. Since we need to know Φ near the sinks (in order to identify Φ with an equipotential surface near the sink and hence an actual drainage sink), we need to obtain rapidly converging series for the RHS of (13) for small x and y. We also need rapidly converging series for the RHS of (12) for small x and y. We consider the series for (12).

ψ for Figure 2a—Observe the following two identities for the ratios of hyperbolic terms in (12). (Proof of the first is left to the reader; the second identity may be written down by inspection of the first, once the first is obtained.)

$$\frac{\sinh [m\pi(h-y)/s]}{\sinh (m\pi h/s)} = e^{-m\pi y/s} - \frac{e^{-m\pi h/s}\sinh (m\pi y/s)}{\sinh (m\pi h/s)} \quad (14)$$

$$\frac{\sinh [m\pi(s-x)/h]}{\sinh (m\pi s/h)} = e^{-m\pi s/h} - \frac{e^{-m\pi s/h}\sinh (m\pi x/h)}{\sinh (m\pi s/h)} \quad (15)$$

Now substitute the RHS of (7) and (8), and of (14) and (15), into (12) to obtain after some rearranging

$$\frac{\pi}{2}\frac{\psi_0 - \psi}{\psi_0} = S_1 - S_2 + S_3 - S_4 - S_5 + S_6 \quad (16)$$

where

$$S_1 = \sum_1^\infty \frac{1}{m}\sin\frac{m\pi x}{s}\, e^{-m\pi y/s} \qquad \text{(use (23))} \quad (17)$$

$$S_2 = \sum_1^\infty \frac{1}{m}\sin\frac{m\pi x}{s}\,\frac{e^{-m\pi h/s}\sinh (m\pi y/s)}{\sinh (m\pi h/s)} \quad (18)$$

$$S_3 = \sum_1^\infty \frac{1}{m}\sin\frac{m\pi y}{h}\, e^{-m\pi x/h} \qquad \text{(use (24))} \quad (19)$$

$$S_4 = \sum_1^\infty \frac{1}{m}\sin\frac{m\pi y}{h}\,\frac{e^{-m\pi s/h}\sinh (m\pi x/h)}{\sinh (m\pi s/h)} \quad (20)$$

$$S_5 = \frac{h}{\pi(b-a)}\sum_1^\infty \frac{1}{m^2}\left(\sin\frac{m\pi b}{h} - \sin\frac{m\pi a}{h}\right) \cdot \sin\frac{m\pi y}{h}\, e^{-m\pi x/h} \quad (21)$$

$$S_6 = \frac{h}{\pi(b-a)}\sum_1^\infty \frac{1}{m^2}\left(\sin\frac{m\pi b}{h} - \sin\frac{m\pi a}{h}\right) \cdot \sin\frac{m\pi a}{h}\,\frac{e^{-m\pi s/h}\sinh (m\pi x/h)}{\sinh (m\pi s/h)} \quad (22)$$

In (16), S_1 and S_2 stem from terms in (12) having coefficients A_m. The remaining terms in (16) stem from terms in (12) having coefficients B_m.

The quantity S_2, as seen in the RHS of (18), sums rapidly because of the factor exp $(-m\pi h/s)$. Also, S_4 and S_6 sum extremely rapidly because of the factor exp $(-m\pi s/h)$. The sums S_1 and S_3 converge very slowly for small x and y, but this is immaterial because, as will be shown in the Appendix (see there Eq. (96) and below), the sums S_1 and S_3 can be obtained in the closed forms

$$S_1 = \tan^{-1}\frac{\sin (\pi x/s)}{e^{\pi y/s} - \cos (\pi x/s)} \quad (23)$$

$$S_3 = \tan^{-1}\frac{\sin (\pi y/h)}{e^{\pi x/h} - \cos (\pi y/h)} \quad (24)$$

The remaining sum to consider, S_5 of (21), does not converge rapidly for small x and y. But neither does it converge very slowly. Slow convergence is prevented by the m^2 in the denominator of the RHS of (21). For practical purposes (21) yields, as it stands, good enough results, without undue labor. Nevertheless the author has obtained a very rapidly converging series for the RHS of (21). It is not a compact expression and its proof requires several pages. To save space the rapidly converging series is not presented. If one sums the first 100 terms of the RHS of (21) as it stands, the absolute value of the error, committed by omitting the remaining terms, will be less than (see *Whittaker* and *Robinson*, 1944, p. 137, Ex. 2)

$$\left(\sum_{101}^\infty \frac{1}{m^2}\right)\frac{h}{\pi(b-a)}\, e^{-101\pi x/h} = 0.005000\,\frac{h}{\pi(b-a)}\, e^{-101\pi x/h} \quad (24a)$$

and hence negligible even if $x = 0$.

Φ for Figure 2a—Observe that the ratios of hyperbolic terms in (13) may be written

$$\frac{\cosh [m\pi(h-y)/s]}{\sinh (m\pi h/x)} = e^{-m\pi y/s} + \frac{e^{-m\pi h/s}\cosh (m\pi y/s)}{\sinh (m\pi h/s)} \quad (25)$$

$$\frac{\cosh [m\pi(s-x)/h]}{\sinh (m\pi s/h)} = e^{-m\pi x/h} + \frac{e^{-m\pi s/h}\cosh (m\pi x/h)}{\sinh (m\pi s/h)} \quad (26)$$

Now substitute the RHS of (7) and (8) and of (25) and (26) into (13), to obtain, after rearranging (and with new symbols V, T_1, T_2, $\cdots$, defined as below)

$$\frac{\pi}{2}\frac{\Phi - C}{\psi_0} = V(x, y) \tag{26a}$$

where

$$V(x, y) = -T_1 - T_2 + T_3 + T_4 - T_5 - T_6 \tag{27}$$

where further

$$T_1 = \sum_1^\infty \frac{1}{m}\cos\frac{m\pi x}{s}\, e^{-m\pi y/s} \qquad \text{(use (34))} \tag{28}$$

$$T_2 = \sum_1^\infty \frac{1}{m}\cos\frac{m\pi x}{s}\, \frac{e^{-m\pi h/s}\cosh(m\pi y/s)}{\sinh(m\pi h/s)} \tag{29}$$

$$T_3 = \sum_1^\infty \frac{1}{m}\cos\frac{m\pi y}{h}\, e^{-m\pi x/h} \qquad \text{(use (35))} \tag{30}$$

$$T_4 = \sum_1^\infty \frac{1}{m}\cos\frac{m\pi y}{h}\, \frac{e^{-m\pi s/h}\cosh(m\pi x/h)}{\sinh(m\pi s/h)} \tag{31}$$

$$T_5 = \frac{h}{\pi(b-a)}\sum_1^\infty \frac{1}{m^2}\left(\sin\frac{m\pi b}{h} - \sin\frac{m\pi a}{h}\right) \cdot \cos\frac{m\pi y}{h}\, e^{-m\pi x/h} \tag{32}$$

$$T_6 = \frac{h}{\pi(b-a)}\sum_1^\infty \frac{1}{m^2}\left(\sin\frac{m\pi b}{h} - \sin\frac{m\pi a}{h}\right) \cdot \cos\frac{m\pi y}{h}\, \frac{e^{-m\pi s/h}\cosh(m\pi x/h)}{\sinh(m\pi s/h)} \tag{33}$$

Comparing (1) and (2) and remembering that ϕ in (2) is a length, observe that Φ and ψ_0 in the LHS of (27) both have the same dimensions, making (as in (15)) the LHS and RHS of (27) dimensionless.

In (28) to (33) the sums T_1 and T_3 are very slowly convergent for small x and y but this does not matter because (see the Appendix, Eq. (97) instead of (28) and (30) we may use

$$T_1 = -\tfrac{1}{2}\ln\left[2e^{-\pi y/s}\left(\cosh\frac{\pi y}{s} - \cos\frac{\pi x}{s}\right)\right] \tag{34}$$

$$T_3 = -\tfrac{1}{2}\ln\left[2e^{-\pi x/h}\left(\cosh\frac{\pi x}{h} - \cos\frac{\pi y}{h}\right)\right] \tag{35}$$

The other sums in (28) to (33) converge rapidly, or at least rapidly enough for our purposes. A rapidly converging, but not very simple series for T_5 may be obtained from the author on request. The absolute value of the error committed by dropping terms beyond the one-hundredth in the RHS of (32) will be less than the RHS of (24a).

ψ and Φ for Figure 2b—The results so far obtained for ψ and Φ are for the general case of Figure 2a. We now obtain expressions for Figures 2b, 2c, $\cdots$, 2g. For Figure 2b, put $a = 0$ and $b = d$ in (16) and (27) and auxiliary equations. The equations will remain unchanged except (21) and (22), and (32) and (33), which become (we use a superscript notation from here on to distinguish special cases; for example the superscript b in the next six equations refers to the problem of Figure 2b)

$$S_5^b = \frac{h}{\pi d}\sum_1^\infty \frac{1}{m^2}\sin\frac{m\pi d}{h}\sin\frac{m\pi y}{h}\, e^{-m\pi x/h} \tag{36}$$

$$S_6^b = \frac{h}{\pi d}\sum_1^\infty \frac{1}{m^2}\sin\frac{m\pi d}{h}\sin\frac{m\pi y}{h} \cdot \frac{e^{-m\pi s/h}\sinh(m\pi x/h)}{\sinh(m\pi s/h)} \tag{37}$$

$$T_5^b = \frac{h}{\pi d}\sum_1^\infty \frac{1}{m^2}\sin\frac{m\pi d}{h}\cos\frac{m\pi y}{h}\, e^{-m\pi x/h} \tag{38}$$

$$T_6^b = \frac{h}{\pi d}\sum_1^\infty \frac{1}{m^2}\sin\frac{m\pi d}{h}\cos\frac{m\pi y}{h} \cdot \frac{e^{-m\pi s/h}\cosh(m\pi x/h)}{\sinh(m\pi s/h)} \tag{39}$$

Therefore (16) becomes

$$\frac{\pi}{2}\frac{\psi_0 - \psi^b}{\psi_0} = S_1 - S_2 + S_3 - S_4 - S_5^b + S_6^b \tag{40}$$

and (26a) and (27) become

$$V^b(x, y) = \frac{\pi}{2}\frac{\Phi - C^b}{\psi_0} = -T_1 - T_2 + T_3 + T_4 - T_5^b - T_6^b \tag{41}$$

ψ and Φ for Figure 2c—Put $d = h$ in (36) to (39) and obtain, since $\sin m\pi = 0$

$$S_5^c = 0, \quad S_6^c = 0, \quad T_5^c = 0, \quad T_6^c = 0 \tag{42}$$

Therefore (16) and (27) become

$$\frac{\pi}{2}\frac{\psi_0 - \psi^c}{\psi_0} = S_1 - S_2 + S_3 - S_4 \tag{43}$$

$$V^c(x, y) = \frac{\pi}{2}\frac{\Phi^c - C^c}{\psi_0} = -T_1 - T_2 + T_3 + T_4 \tag{44}$$

ψ and Φ for Figure 2d—Let in (21) and (22), $a = 0$, and $b = d$ and then let $d \to 0$, so that (with d dropping out of results as it should)

$$\frac{h}{\pi(b-a)}\frac{1}{m^2}\left(\sin\frac{m\pi b}{h} - \sin\frac{m\pi a}{h}\right) = \frac{h}{\pi d}\frac{1}{m^2}\sin\frac{m\pi d}{h} \to \frac{h}{\pi d}\frac{1}{m^2}\frac{m\pi d}{h} = \frac{1}{m} \tag{45}$$

Therefore, using (45) in (21) and (22) and comparing with (19) and (20), find

$$S_6^d = S_4, \qquad S_5^d = S_3 \tag{46}$$

so that (16) becomes

$$\frac{\pi}{2}\frac{\psi_0 - \psi^d}{\psi_0} = S_1 - S_2 \tag{47}$$

Similarly

$$T_6^d = T_4, \qquad T_5^d = T_3 \tag{48}$$

so that (27) becomes

$$V^d(x, y) = \frac{\pi}{2}\frac{\Phi^d - C^d}{\psi_0} = -T_1 - T_2 \tag{49}$$

ψ and Φ for Figure 2e—Comparing Figures 2a and 2e, put in (21) and (22) $b = h$ and $a = h - g$ and obtain after trigonometric reduction

$$S_5^e = \frac{h}{\pi g}\sum_1^\infty (-1)^m \frac{1}{m^2} \sin\frac{m\pi g}{h} \sin\frac{m\pi y}{h} e^{-m\pi x/h} \tag{50}$$

$$S_6^e = \frac{h}{\pi g}\sum_1^\infty (-1)^m \frac{1}{m^2} \sin\frac{m\pi g}{h} \sin\frac{m\pi y}{h} \cdot \frac{e^{-m\pi s/h}\sinh(m\pi x/h)}{\sinh(m\pi s/h)} \tag{51}$$

Whence (16) becomes

$$\frac{\pi}{2}\frac{\psi_0 - \psi^e}{\psi_0} = S_1 - S_2 + S_3 - S_4 - S_5^e + S_6^e \tag{52}$$

Similarly, we find from (32) and (33)

$$T_5^e = \frac{h}{\pi g}\sum_1^\infty (-1)^m \frac{1}{m^2} \sin\frac{m\pi g}{h} \cos\frac{m\pi y}{h} e^{-m\pi x/h} \tag{53}$$

$$T_6^e = \frac{h}{\pi g}\sum_1^\infty (-1)^m \frac{1}{m^2} \sin\frac{m\pi g}{h} \cos\frac{m\pi y}{h} \cdot \frac{e^{-m\pi s/h}\cosh(m\pi x/h)}{\sinh(m\pi s/h)} \tag{54}$$

and (27) becomes

$$V^e = \frac{\pi}{2}\frac{\Phi^e - C^e}{\psi_0} = -T_1 - T_2 + T_3 + T_4 - T_5^e - T_6^e \tag{55}$$

ψ and Φ for Figure 2f—In (50), (51), (53), and (54), let $g \to 0$ so that $\sin(m\pi g/h) \to m\pi g/h$ and find (with g now dropping out of results as it should)

$$S_5^f = \sum_1^\infty (-1)^m \frac{1}{m} \sin\frac{m\pi y}{h} e^{-m\pi x/h} \qquad \text{(use (62))} \tag{56}$$

$$S_6^f = \sum_1^\infty (-1)^m \frac{1}{m} \sin\frac{m\pi y}{h} \frac{e^{-m\pi s/h}\sinh(m\pi x/h)}{\sinh(m\pi s/h)} \tag{57}$$

$$T_5^f = \sum_1^\infty (-1)^m \frac{1}{m} \cos\frac{m\pi y}{h} e^{-m\pi x/h} \qquad \text{(use (63))} \tag{58}$$

$$T_6^f = \sum_1^\infty (-1)^m \frac{1}{m} \cos\frac{m\pi y}{h} \frac{e^{-m\pi s/h}\cosh(m\pi x/h)}{\sinh(m\pi s/h)} \tag{59}$$

Therefore (16) and (27) become, respectively

$$\frac{\pi}{2}\frac{\psi_0 - \psi^f}{\psi_0} = S_1 - S_2 + S_3 - S_4 - S_5^f + S_6^f \tag{60}$$

$$V^f = \frac{\pi}{2}\frac{\Phi^f - C^f}{\psi_0} = -T_1 - T_2 + T_3 + T_4 - T_5^f - T_6^f \qquad \text{(see (64))} \tag{61}$$

Notice that the sums in (56) and (58) converge very slowly for small x/h. This does not matter since they can be summed analytically (see (98) and (100)) with the results

$$S_5^f = -\tan^{-1}\frac{\sin(\pi y/h)}{e^{-\pi x/h} - \cos(\pi y/h)} + \tan^{-1}\frac{\sin(2\pi y/h)}{e^{-2\pi x/h} - \cos(2\pi y/h)} \tag{62}$$

$$T_5^f = \tfrac{1}{2}\ln\left[2e^{-\pi x/h}\left(\cosh\frac{\pi x}{h} - \cos\frac{\pi y}{h}\right)\right] - \tfrac{1}{2}\ln\left[2e^{-2\pi x/h}\left(\cosh\frac{2\pi x}{h} - \cos\frac{2\pi y}{h}\right)\right] \tag{63}$$

Eq. (63) could be further simplified but it is better, in order to simplify the expression $(T_3 + T_5^f)$ in (61), to leave (63) as it stands. We then find for $(T_3 + T_5^f)$, in view of (36) and (6)

$$T_3 + T_5^f = -\tfrac{1}{2}\left[\ln 2 - \frac{2\pi x}{h} + \ln\left(\cosh\frac{2\pi x}{h} - \cos\frac{2\pi y}{h}\right)\right] \tag{64}$$

ψ and Φ for Figure 2g—For our last case we refer to Figure 2a and denote the semiheight $(b - a)/2$ of the strip by Δ. That is, $b - a = 2\Delta$, $b = c + \Delta$, $a = c - \Delta$. Therefore in (21), (22), (32) and (34) we find upon letting $\Delta \to 0$

$$\frac{h}{\pi(b-a)}\left(\sin\frac{m\pi b}{h} - \sin\frac{m\pi a}{h}\right) = \frac{h}{2\pi\Delta}\left[\sin\frac{m\pi(c+\Delta)}{h} - \sin\frac{m\pi(c-\Delta)}{h}\right] = \frac{h}{2\pi\Delta} 2\sin\frac{m\pi\Delta}{h}\cos\frac{m\pi c}{h} \to m\cos\frac{m\pi c}{h}$$

So that (with Δ dropping out of the analysis, as it should)

$$S_5^g = \sum_1^\infty \frac{1}{m}\cos\frac{m\pi c}{h}\sin\frac{m\pi y}{h} e^{-m\pi x/h} \qquad \text{(see (71))} \tag{65}$$

$$S_6{}^g = \sum_1^\infty \frac{1}{m} \cos \frac{m\pi c}{h} \sin \frac{m\pi y}{h} \frac{e^{-m\pi s/h} \sinh (m\pi x/h)}{\sinh (m\pi s/h)} \qquad (66)$$

$$T_5{}^g = \sum_1^\infty \frac{1}{m} \cos \frac{m\pi c}{h} \cos \frac{m\pi y}{h} e^{-m\pi x/h} \qquad \text{(see (72))} \qquad (67)$$

$$T_6{}^g = \sum_1^\infty \frac{1}{m} \cos \frac{m\pi c}{h} \cos \frac{m\pi y}{h} \frac{e^{-m\pi s/h} \cosh (m\pi x/h)}{\sinh (m\pi s/h)} \qquad (68)$$

Accordingly (16) and (27) become

$$\frac{\pi}{2} \frac{\psi_0 - \psi^g}{\psi_0} = S_1 - S_2 + S_3 - S_4 - S_5{}^g + S_6{}^g \qquad (69)$$

$$V^g(x, y) = \frac{\pi}{2} \frac{\Phi^g - C^g}{\psi_0}$$

$$= -T_1 - T_2 + T_3 + T_4 - T_5{}^g - T_6{}^g \qquad (70)$$

The sums in (65) and (67) converge slowly for small x and y. Therefore for small x and y (see (101) and (102)) use

$$S_5{}^g = \tfrac{1}{2} \tan^{-1} \frac{\sin [\pi(y + c)/h]}{e^{\pi x/h} - \cos [\pi(y + c)/h]} + \tfrac{1}{2} \tan^{-1} \frac{\sin [\pi(y - c)/h]}{e^{\pi x/h} - \cos [\pi(y - c)/h]} \qquad (71)$$

$$T_5{}^g = -\tfrac{1}{4} \ln \left\{ 2e^{-\pi x/h} \left[\cosh \frac{\pi x}{h} - \cos \frac{\pi(y + c)}{h} \right] \right\} - \tfrac{1}{4} \ln \left\{ 2e^{-\pi x/h} \left[\cosh \frac{\pi x}{h} - \cos \frac{\pi(y - c)}{h} \right] \right\} \qquad (72)$$

Notice that putting $c = 0$ in the RHS of (65) yields S_3 of (19). That is $S_5{}^g |_{c=0} = S_3$; or since by the second of (46) we have $S_3 = S_5{}^d$, we find

$$S_5{}^g |_{c=0} = S_5{}^d$$

which, comparing Figures 2d and 2g, is a check on previous work. Similarly $S_6{}^g$, $T_5{}^g$, and $T_6{}^g$ go over to $S_6{}^d$, $T_5{}^d$, and $T_6{}^d$ when $c = 0$, as they should.

Evaluation of the constant C—In considering the constant C the situations for Figures 2b, 2c and 2d and for Figures 2a, 2e, 2f, and 2g are considered separately. For Figures 2b, 2c, and 2d, let $\Phi(x_0, 0)$ be the value of an equipotential surface passing through the point (r, O), and let us identify the equipotential passing through (r, O) with the shape of a drainage facility assumed running full to the level $y = 0$; that is, r is the semi-width of the ditch or tube. Then since it has been agreed (see below (2)) to take the reference level at the x-axis, we see that the left hand equality of (41) becomes

$$\frac{\pi}{2} \frac{O - C^b}{\psi_0} = V^b(r, O)$$

That is

$$C^b = -(2/\pi)\psi_0 V^b(r, O) \qquad (73)$$

where $V^b(r, O)$ is to be obtained from the *RHS* of (41) by putting x and y in the T's respectively equal to r and O. Similarly one obtains from (44) and (49)

$$C^c = -(2/\pi)\psi_0 V^c(r, O) \qquad (74)$$

$$C^d = -(2/\pi)\psi_0 V^d(r, O) \qquad (75)$$

where $V^c(r, O)$ is evaluated from the RHS of (44) and $V^d(r, O)$ from the RHS of (49).

To obtain C for Figures 2a, 2e, 2f, and 2g we observe that the water table stands above the sink at all points, including points immediately over the sink. Therefore we cannot, as before, simultaneously identify a point on the sink with a point on the water table. Instead we must take, in (26), $V(x, y) = V(0, 0)$ when $\Phi = 0$. We obtain then for the cases a, e, f, and g, using a composite notation to show four equations in one

$$C^{aefg} = -(2/\pi)\psi_0 V^{aefg}(0, 0) \qquad (76)$$

where V^a is obtained from (27), (34), (29), (35), (31), (32), and (33); $V^e(0, 0)$ from (44), (34), (29), (35), and (31); $V^f(0, 0)$ from (61), (34), (29), (35), and (31); and $V^g(0, 0)$ from (70), (34), (29), (35), (31), (72), (68), (63), and (59).

In (27), (44), (61), and (70), notice that

$$(-T_1 + T_3)$$

in view of (34) and (35) simplifies to

$$-T_1 + T_3 = \tfrac{1}{2} \ln \frac{e^{-\pi y/s} [\cosh (\pi y/s) - \cos (\pi x/s)]}{e^{-\pi x/h} [\cosh (\pi x/h) - \cos (\pi y/h)]}$$

an expression which when x and y both approach zero reduces, in view of *Dwight* [1947, formulas 415.02, 675.2 where cubed terms are to be neglected] to the form

$$-T_1 + T_3 = \ln \frac{h}{s} + \frac{\pi}{2} \left(\frac{x}{h} - \frac{y}{s} \right), \qquad (x, y \to 0)$$

In particular when x and y are both zero, as for $V(0, 0)$, we have

$$-T_1 + T_3 = \ln \frac{h}{s}, \qquad (x, y = 0)$$

Formulas for the hydraulic head—Using the values of C^{bcd} of (73), (74), and (75) in the equalities at the left of (41), (44), and (49), and using then (1) and (2) we find

$$\phi^{bcd}(x, y) = \frac{2sR}{k} \frac{1}{\pi} [V^{bcd}(x, y) - V^{bcd}(r, O)] \qquad (77)$$

and similarly from (76), and from (26a), where the superscript a on C and V is to be understood), and further from (55), (61), (70), (1), and (2) we find

$$\phi^{aefg}(x, y) = \frac{2sR}{k}\frac{1}{\pi}[V^{aefg}(x, y) - V^{aefg}(0, 0)] \quad (78)$$
